16.6.4.4 Micelles. Surfactants added to solids at concentrations below their CMC are often used to improve drug wettability, that is, to reduce the interfacial tension between the drug and dissolution medium (Section 21.6.2.1). Above their CMC, surfactants form micelles, which can solubilize poorly soluble drugs in water [337]. In micelles, the hydrophobic tails of the surfactants point to the inside, and depending on their polarity, drugs may get inserted into various regions of the micelles. Common surfactants used for solubilization are nonionic (e.g., Tweens, Spans, Solutol HS-15, VitE-TPGS, Pluronic F68), anionic (e.g., sodium lauryl sulfate), cationic (e.g., cetyltrimethylammonium bromide), or zwitterionic (e.g., phospholipids) [301]. Above CMC, drug concentration in solution usually increases linearly with surfactant concentration. Inversely, drug solubility decreases on dilution of micelle formulations, and thus drug may precipitate in intestinal fluids. In general, the lower the CMC is, the more stable the micelles are and hence the more they can be diluted before micelles break apart. Therefore, nonionic surfactants with low CMCs are often better solubilizers than ionic surfactants. Cosolvents may be combined with surfactants to improve solubility [338]. For ionizable compounds, pH control may also be used to further enhance drug solubility and/or the drug load of micelles. However, especially for ionic surfactants, pH, ionic strength, and counter ions need to be controlled carefully to optimize micellar solubilization. The overall gain in oral drug absorption with micellar solutions will depend on the degree and duration of supersaturation that can be achieved *in vivo* (Section 16.6.5). However, absorption might also be reduced because of the lower diffusivity of drug-loaded micelles as discussed in Section 16.5.4.

16.6.4.5 Lipids. Many poorly water-soluble, lipophilic drugs may be formulated in lipidic drug delivery systems, and extensive reviews are available in this area [306,307,339,340]. Lipid formulations mimic to some extent the solubilization of drugs by food and can reduce or even eliminate the difference in drug absorption between fed and fasted subjects. Ideally, they maintain drug in solution during dispersion and digestion before absorption. Lipid formulations may include a broad variety of excipients ranging from triglycerides, mono- and diglycerides, lipophilic surfactants, hydrophilic surfactants, to cosolvents. Their *in vivo* performance depends on the dispersion and dilution of the formulation and on the influence of digestion on drug solubilization. Pouton suggested the Lipid Formulation Classification System (LFCS) to identify the factors that are likely to affect performance *in vivo*. Type I represent pure oil formulations that can only be used for highly lipophilic drugs. They are nondispersible, and digestion is needed for drug release. Type II formulations additionally contain water-insoluble surfactants (hydrophilic-lipophilic-balance (HLB) <12). They are water-insoluble self-emulsifying drug delivery systems (SEDDS), which form

turbid oil-in-water dispersions with particle sizes >100 nm without losing solvent capacity. Digestibility is not crucial for drug release but is likely to occur. Depending on the composition, viscous liquid crystalline gels may form at the oil–water interface. Type III systems are SEDDS or self-microemulsifying drug delivery systems (SMEDDS), which contain water-soluble surfactants ($\text{HLB} > 12$) and/or cosolvents. They form clear or almost-clear dispersions on dilution with particle of size <100 nm, and digestion is not crucial for drug absorption. Smaller particles have a larger surface area, which facilitates digestion and a more rapid and uniform drug release. Type III formulations can be further segregated into Types IIIA and IIIB, the latter representing more hydrophilic systems with higher amounts of hydrophilic surfactants and cosolvents and less oils. Type IV formulations contain no oil and consist of water-soluble and/or water-insoluble surfactants with or without cosolvents. On dispersion, these systems form micellar solutions, a loss of solvent capacity is likely, and hence this type bears a high risk of drug precipitation. Digestion is not required for drug absorption. Type IV systems are often used for drugs that are hydrophobic but not lipophilic. Cosolvents are added to facilitate dispersion and to reduce variability and irritancy caused by high local concentrations of surfactant.

The design of lipid formulations is not trivial. First, a vehicle has to be identified, which completely dissolves the target dose. Then, *in vitro* dilution studies have to be performed in simulated intestinal media to study the phase changes of the formulation and to estimate the fate of the drug. If precipitation occurs, the advantage of lipid formulation is largely lost. Relevant dilution ranges to look at may differ depending on the target species. To estimate the likelihood of precipitation, equilibrium solubility studies can be an alternative to these kinetic solubility studies. Here, compound solubility is measured in various dilutions of the formulation [341]. For formulations that require digestion for drug release, *in vitro* lipolysis studies should also be performed. Other questions to address are the importance of lipid particle size for absorption, the desired release kinetics, and the ability of certain lipids to support lymphatic transport [306]. Since dispersibility, dilution factors, and digestibility of formulation may vary in different species, the performance of formulations may differ [339].

16.6.5 Formulation Strategies Inhibiting Drug Precipitation

Most formulation strategies described before are designed to maximize the concentration of the drug at the site of absorption, thereby increasing the absorption rate (Eq. 16.4). As shown in Fig. 16.9, formulations either increase the dissolution rate of the drug to maintain C_s (shift from 2 to 1) and/or increasing its apparent or kinetic solubility above C_s (3) to enhance the concentration gradient across the intestinal membrane (7). If the local drug concentration exceeds C_s in the GIT, supersaturated solutions are formed (Section 16.5.1.1). These systems are inherently thermodynamically unstable, and thus the drug may rapidly (4), slowly (5), or not at all (6) precipitate during the intestinal transit, which can lead to variable absorption. Precipitation reduces free drug concentration, and if it happens at the surface of a dosage form, dissolution of additional drug may be prevented. In the worst case, precipitation may even decrease drug solubility below C_s , for example, if drug precipitates as agglomerate of large particles with slow dissolution rate (8). The risk for drug precipitation increases with the supersaturation ratio (Section 16.5.1.1) and it decreases with the viscosity of the medium. Supersaturated solutions can only be created from forms of the drugs that have a higher

energy than the thermodynamically most stable crystalline form. These high energy forms work like a “spring” (Fig. 16.9). A “spring” can be a higher energy solid (e.g., amorphous form, salts, solid dispersions) (Sections 16.6.3.2 and 16.6.3.3) or a solution (e.g., cosolvents, lipids) (Section 16.6.4). Higher energy forms are usually introduced by the formulation; however, they may also result from physiological processes. An example is a weak base that completely dissolves at the acidic pH of the stomach, then forms a supersaturated solution at the higher pH values in the small intestine, and eventually precipitates again as base [285]. Supersaturation enhances the absorption rate (Eq. 16.4) of drugs in all BCS classes (Section 16.4.1), since concentrations higher than C_S will always increase the driving force for molecules for transit into and across biological membranes (7). Once achieved, intraluminal supersaturated states have to be maintained for a period sufficient for absorption. The challenge for formulators is to identify appropriate pharmaceutical excipients that hinder (6) or slow down (5) nucleation and crystal growth and act as “parachutes” or precipitation inhibitors for drugs [134,342,343]. Precipitation inhibitors can act at different levels. They may increase drug solubility or medium viscosity, bind to the interface between liquid and solute aggregates (decrease nucleation), adsorb to the medium–crystal interface (hinder crystal growth) and/or change the solvation at crystal–liquid interface (affect integration of drug molecules into crystal) [134]. Commonly used classes of excipients are polymers (e.g., HPMC, PVP, PEG), surfactants (e.g., SDS, Cremophor RH40), and cyclodextrins (e.g., HP- β -CD, SBE- β -CD), which are also regularly used in high energy solid (Section 16.6.3.3) and solution formulations (Section 16.6.4) to enhance dissolution rate and/or solubility. Box and Comer [235] suggested that slowly precipitating and dissolving acids, bases, and ampholytes with high MPs of free form (“chasers”) may be better candidates for supersaturating systems than fast-precipitating, slowly dissolving bases with low MP (“nonchasers”). A number of solvent quench approaches are now available for *in vitro* screening of crystallization inhibitors [134,301,342,344] and several methods have recently been reviewed by Dai [345]. The impact of excipients on solubility may also be tested in any of the solubility assays discussed in Section 16.5.3. The design of predictive *in vitro* assays is challenging since a number of factors, such as drug, inhibitor, and medium (volume, pH, etc.), affect their outcome; however, often, excellent IVIVCs have been obtained [342,346–348].

16.7 PRECLINICAL FORMULATIONS FOR CANDIDATE PROFILING

The development of nonclinical formulations for dosing in animal is usually very pragmatic and dictated by the physicochemical properties of the compound, dosing route, dose, species, type of study, and time pressure of the project. If feasible, it starts with aqueous solutions with or without pH adjustment, cosolvents, and/or surfactants (Section 16.6.4). Compounds that are not soluble enough may be dosed in lipidic systems if properties and dose are compatible (section 16.6.4.5). For solutions, the precipitation behavior on dilution needs to be tested to avoid side effects after parenteral dosing or reduced BA after oral administration (Section 16.6.5). If a dose cannot be completely solubilized, suspensions and nanosuspensions are used as an alternative; the latter may also be used for parenteral dosing (Section 16.6.3.1). To avoid surprises and to aid interpretation, the properties of the initial and final (or precipitated) solid should be monitored, for the reasons discussed before. Many decision trees have been

developed for formulation selection (Section 16.6.2), and measurement of solubility (Section 16.5.3) and dissolution (Section 16.5.4) are key elements in most of them. In many instances, combinations of the formulation approaches discussed in Section 16.6 are used to achieve synergistic effects; however, a scientist should be aware of potential interactions in such systems, for example, loss of solubilization capacity by binding of surfactants to cyclodextrins [256] or reduction of preservative concentration by cocrystal formation [330]. Since formulation strategies depend on drug properties, dose, and species, and, for oral absorption, on the identified rate-limiting steps (Section 16.3), approaches may change with each and any of these factors. Rat and mouse are usually dosed with solutions or suspension, while larger species may also receive capsules. Important aspects for all formulations are sufficient chemical stability of the drug in the vehicle, optimal *in vivo* exposure at the target site, accurate dosing, no vehicle effect on PD parameter [300,310,324], and minimal toxic effects of the vehicle alone. Food effects [349–351] and species physiology also need to be considered. Comprehensive summaries of GIT physiology are available for human [352], cynomolgus monkey [353–356], rat [51,56,357], mouse [51], and dog [349,358]. Reports comparing several species [42,54,58,299,359] or only two species are available, for example, human–dog [28], human–cynomolgus monkey [360], human–rat [361], dog–cat [54] or rat–mouse [51].

The development of suitable formulations for toxicology is challenging since doses are high and excipient amounts often need to be high for sufficient and dose-linear exposure. An overview of commonly used excipients for preclinical PK, PD, and toxicity studies and use ranges can be found in Ref. 298,299,301,303,311. Scientists should always be aware of the maximum tolerated dose of excipient(s), and in short-term studies, as a rule of thumb, the amount of an excipient in formulations should not exceed one-twentieth of its LD₅₀ value (lethal dose for 50% of those exposed to a toxic agent). In chronic studies, other criteria may apply. Two smaller sets of commonly used non-clinical vehicles have been published by Maas *et al.* [298] and Neervannan [299], and an extensive list is available from Gad *et al.* [311]; the latter also includes maximum tolerated use levels by species, route, and duration of study, with accompanying dose-limiting toxicity. Excipients and vehicles for parenteral administration have been discussed in detail by Strickley [313]. Furthermore, guidelines have been suggested that recommend for common laboratory species, the maximal dosing volumes for different routes of administration as well as the volumes for blood sampling [311,362].

Researchers should be aware of the fact that the criteria for formulations for animal and human studies may differ and that right first-time formulations are rare [96,304]. One reason is the dose range required for testing, which is often several-fold higher in animal than in human and may necessitate different formulation approaches. Another one can be formulation related, for example, capsules cannot be administered to mice. Often, timelines also play a role, and enabling technologies such as polymer-stabilized solid solutions are only feasible in later development phases. In many instances, microsuspensions with crystalline solids are a useful starting point to estimate the developability of a simple human formulation since they represent a disintegrated dosage form such as tablet or capsule. If they give a sufficient exposure, clinical formulation development is usually not an issue. If solutions are used in early studies, results should be reaffirmed as soon as possible using characterized suspensions.

16.8 FORMULATION AND EXCIPIENT EFFECTS ON DRUG DISPOSITION

Both rate and extent of oral absorption of potential drug candidates can be significantly influenced by solid state properties, type of formulation, and excipients used, as discussed in previous sections. As a result, the intrinsic PK and PD characteristics of a drug may be altered unintentionally by influencing its absorption, distribution, metabolism, and/or elimination [6,297,308,310,363–365]. An in-depth discussion of all formulation- and excipient-related effects is far beyond the scope of this review. However, a few important aspects are highlighted below to increase the awareness of pharmaceutical scientists for formulation effects on drug disposition, to aid in the interpretation of drug metabolism and pharmacokinetics (DMPK) and PD results, and to reduce the risk of incorrect drug candidate classification.

For compounds with dissolution-limited absorption, an increase in dissolution rate by any of the formulation principles described in Section 16.6.3 is expected to result in an earlier peak of absorption and a larger AUC if C_s can be maintained throughout absorption. If drugs exhibit solubility- or permeability-limited absorption (Section 16.3), an increase of apparent/kinetic drug solubility in the GIT by formulation (Sections 16.6.3, 16.6.4, and 16.6.5) is likely to increase the $C_{\max}$ because of the higher concentration gradient across the membrane (Fig. 16.9). An increase in AUC is expected if the supersaturated state can be maintained, for example, by precipitation inhibitors (Section 16.6.5). In contrast, the benefit of a solution formulation (Section 16.6.4) may be completely lost on drug precipitation. If drug precipitates, for example, as low energy, crystalline, large, or aggregated particles, exposure may even be lower than with a defined suspension of finely distributed small particles. In general, particle size and polymorphic form of a drug in suspensions may significantly impact $C_{\max}$, $T_{\max}$, and AUC [261,286,366]. Suspensions of the same drug prepared from amorphous or crystalline forms [367] or from different polymorphic forms [366] or salts [327,367] may show completely different PK profiles. If this substantial impact of solid state properties on drug disposition is ignored for the ranking of preclinical drug candidates, an inappropriate compound might be selected for development.

Increases in intestinal drug solubility may also affect absorption by other mechanisms. If drugs are substrates for absorptive transporters, a less than dose-proportional increase may be observed with increasing doses of completely solubilized drug due to a saturation of the active transporter. On the contrary, drugs that are substrates for efflux transporters (e.g., P-glycoprotein (P-gp)) and/or for metabolic enzymes (e.g., CYP3A4) may show a more than dose-proportional increase in drug absorption with increasing concentrations since these mechanisms will be saturated above a certain level [368].

Furthermore, a number of excipients commonly used in solubility-enhancing formulations (e.g., VitE-TPGS, Cremophor EL, Tween 80, Solutol HS15) are also reported to enhance drug absorption by direct inhibition of efflux transporters and/or metabolic enzymes [6,300]. However, depending on drug properties and surfactant used, surfactant micelles may also trap drugs and reduce their absorption [364,369]. For example, Cremophor EL decreased digoxin absorption and shifted $T_{\max}$ to later times, while VitE-TPGS increased its absorption and decreased $T_{\max}$ [370], although both surfactants enhance drug solubility and inhibit P-gp. In many cases, it is difficult to distinguish between the direct effects of excipients on transporters or metabolic enzymes and their

indirect effects on drug solubilization. In later development phases, controlled-release delivery systems may be used to modify SITT, to deliver drugs to specific regions of the GIT, or to bypass metabolism or efflux pumps [74,308]. Similar to the oral route, surfactants may also influence the disposition of solubilized drug after parenteral administration, and huge differences have been reported, for example, in metabolism, excretion, and distribution of drugs bound to Tween 80 or Cremophor EL micelles [364].

Other commonly used formulation constituents may also alter drug absorption and drug disposition. For example, CDs may reduce oral BA if the administered CD concentrations are too high [6,231]. CDs may also influence GI motility and liver function at higher doses [310]. Similarly, cosolvents (e.g., PEG400, DMSO, ethanol), HPMC, and fat emulsions may change GI, renal, and/or liver parameters after application of a certain threshold [6,310,371,372]. Therefore, vehicle-dependent side effects should be known, and particularly in PD studies, the influence of placebo vehicle on the measured parameter should be evaluated; for example, SB β -CD, Tween 80, and HPMC were reported to decrease blood glucose after oral or parenteral administration [299,310], an effect that might be detrimental in projects hunting for glucose-lowering drugs.

Food adds further complexity to oral absorption studies. A number of postprandial changes in the GIT may affect the rate and extent of drug absorption, for example, slower gastric emptying time, pH shifts in the GIT, saturation of uptake/efflux transporters or of metabolism by food components, and enhanced dissolution/solubilization by increased bile flow, lipids, and lipolysis products. Extensive reviews of the different mechanisms for food–drug interactions and of related key physicochemical parameters of drugs in the frame of BCS and BDDCS classification (Sections 16.4.1 and 16.4.2) can be found elsewhere [20,314,368,373,374]. Lipid formulations may often have effects similar to food and may be used to target highly lipophilic drugs to the lymphatic system, to bypass liver first-pass metabolism, to increase absorption, or to modulate PK parameters [300,306,375].

Overall, the effects of formulation and food on absorption *in vivo* are clearly complex and may be multiple. Effects on drug disposition are more likely in early development programs where typically larger amounts of excipients are administered and studies are often less well controlled. Scientist should be aware of the fact that compound ranking or selection based on PK and PD data generated with different compound batches, formulation principles and/or compositions, administration volumes, or nutrition conditions is prone to errors. Therefore, a systematic, standardized approach for formulation preparation, administration, and data reporting should be established to allow a more realistic comparison of drug candidates and to reduce the overall risk for selecting the wrong candidate for development. There is probably no “universal” vehicle that can be used for all compounds or for all studies; however, a rational study design and selection of excipients and formulations will certainly help to minimize vehicle-dependent side effects and wrong decisions.

16.9 CONCLUSIONS AND FUTURE PERSPECTIVES

The awareness of scientists for preclinical formulation aspects has certainly increased in most pharmaceutical organizations. Discovery scientists now start to understand the impact of solid state properties and of formulation on the outcome of animal studies

and on preclinical attrition rate, and development functions recognize that putting more resources into early discovery can avoid problems and delays downstream in drug development. Consequently, development scientists are now more engaged already during early discovery stages to identify, address, and overcome compound liabilities together with their discovery colleagues to increase the overall chances for success. This process is more data driven than ever before, and an early identification of potential compound limitations such as dissolution, solubility, permeability, or metabolism is essential. Particularly, the growing number of BCS class 2 compounds necessitates thorough measurement of drug solubility and dissolution early on; protocols of different complexity and for different scales are now available. For scientists in pharmaceutical industry, a profound understanding of the advantages, disadvantages, and limitations of the various methodologies and awareness of the different types of solubility and dissolution is a must. It is the basis for a meaningful interpretation of solubility/dissolution data and for a conscious decision on which drug delivery technology to follow or to develop. Furthermore, awareness of the impact of the solid state properties of a compound (initial or created by precipitation) and of the formulation (type and/or excipients used) on PK/PD properties (e.g., $C_{\max}$, $T_{\max}$, AUC) will reduce the risk to misinterpret data from *in vivo* studies, to select the wrong candidate for development, or to eliminate a potentially promising candidate because of low exposure. In this context, the BCS and BDDCS are useful for both discovery and development to categorize or rank-order compounds and to communicate potential development risks to the organization. If the required human dose estimate for BCS/BDDCS is not yet available, MAD may be used in a first instance for compound ranking and for estimating required technologies and developability. Overall, conscious efforts should be made to control solid state properties already from the beginning and whenever feasible, “simple” suspension formulations should be applied in nonclinical studies early on, since they are closest to a disintegrating tablet in later phases. Enabling formulations such as solid solutions, cosolvent solutions, or lipidic formulations may mask compound liabilities if they are used too early or at random, and they should only be applied to improve exposure if the rate-limiting steps in drug absorption have been understood and formulation type and excipients have been selected accordingly. Today’s drug discovery and development process is complex and challenging for scientists in the respective functions. However, in the future, scientists will clearly need to expand their knowledge beyond their traditional core competencies, and only with the combined efforts of both discovery and development scientists, companies will be able to identify efficacious molecules, to transform them into customized drug products for testing in animals and humans, and to bring them to the market in a timely manner.

17.1 INTRODUCTION

The central nervous system (CNS) is one of the most challenging therapeutic areas and many brain diseases still do not have adequate treatments. The major hurdles of discovering new CNS drugs, particularly in the area of neurodegeneration, are that there are few animal disease models and drugs must cross the blood–brain barrier (BBB) to reach the therapeutic targets.

The brain is highly protected anatomically to physical injury by the skull and to chemical insult by two major barriers, namely the BBB and the blood–cerebrospinal fluid barrier (BCSFB). The BBB is formed by the endothelium lining of the cerebral capillaries, while the BCSFB is formed by the epithelium of the choroid plexus (CP) [1]. CP consists of many capillaries, separated from the ventricles by choroid epithelial cells. The BBB and BCSFB represent physical and biological barriers that restrict and regulate the penetration of compounds from blood into and out of the brain intracellular fluid (ICF), interstitial fluid (ISF), and cerebrospinal fluid (CSF), respectively, and maintain the homeostasis of the brain and CSF microenvironments. Therefore, unlike in systemic circulation, the pharmacokinetics (PK) of a drug in brain is complicated by multiple compartments created by the BBB and the BCSFB. A great amount of research went into understanding the properties of BBB and BCSFB. The relationship between drug concentrations in blood, ISF, and CSF can be delineated into a three-compartment model (Fig. 17.1).

Figure 17.1 A three-compartment model illustrating unbound drug transfer between plasma, brain (ISF and ICF), and CSF. BBB, blood–brain barrier; BCSFB, blood–cerebrospinal fluid barrier; $C_{p,u}$, plasma unbound drug concentration; $C_{b,u}$, brain unbound drug concentration; C_{CSF} , CSF drug concentration.

For many physiological membranes, the unbound drug concentrations are equal on both sides at steady state. However, at the BBB and BCSFB, the contributions of active influx transporters, efflux transporters, and tight junctions between brain endothelial cells can cause, for some compounds, the unbound drug concentrations to be unequal across the BBB or the BCSFB. Metabolism within the CNS (very rare) and transport to CSF via ISF bulk flow may also contribute to disequilibrium of unbound drug concentrations in the blood, brain (ISF and ICF), and CSF compartments.

From a PK and pharmacodynamic (PD) perspective, the purpose of assessing brain penetration of a drug is to understand drug exposure at the target cellular locale. According to the free drug hypothesis, only unbound drug at the target cellular locale is available for the pharmacologic interaction [2]. The relative importance of unbound drug concentrations in different brain compartments depends on where the relevant target receptors are situated. If the drug is actively transported across the cell membrane, ICF concentrations could be expected to differ from brain ISF concentrations.

In this chapter, we discuss the critical elements for brain penetration and methodologies in assessing brain exposure. Retroanalysis on the prediction success for brain penetration of Pfizer CNS drug candidates and lessons learned, as well as screening strategies and future prospects in the BBB will be highlighted.

17.2 IMPORTANT PARAMETERS GOVERN BRAIN PENETRATION

The fact that CNS-targeted drugs require good brain penetration is unequivocal. However, what is unclear is which parameters should be used to define “good” brain penetration. Ultimately, it is the free drug concentration at the site of action in the brain that exerts pharmacological activity *in vivo* [2]. There are three important parameters that characterize brain penetration: rate, extent, and brain tissue binding [1]. Rate is how fast compound molecules enter the brain, extent is how many in the brain at steady state, and brain tissue binding is how many molecules are bound to brain tissue compared with unbound in solution [3].

For the extent of brain penetration, the total brain concentration-to-total plasma concentration ratio (also known as total B/P or K_p) is a common parameter used to describe and evaluate brain penetration. A compound is deemed “brain penetrant” if its total B/P is >0.04 , because the cerebral blood volume is approximately 4% of the total brain volume. However, a ratio significantly >1.0 is often observed [4]. Does this indicate that drug molecules are being actively taken up into the brain? No, active uptake is not the case for a majority of drugs. Instead, the higher total B/P ratio is often owing to a significantly higher nonspecific binding of drug molecules to brain tissue than to plasma protein. An experiment conducted by Maurer *et al.* [5] explicitly revealed how nonspecific bindings can confound brain penetration assessment if it is based on the total B/P ratio. In the study, 32 structurally diverse CNS drugs were used. Their total B/P ratios were found to range from 0.06 to 24 after subcutaneous administration in mice [6]. Their nonspecific bindings in mouse plasma and brain homogenate were determined using equilibrium dialysis methodology, and not surprisingly, after corrected with binding factors, their free brain concentration-to-free plasma concentration ratios (also known as free B/P or C_{bu}/C_{pu} or $K_{p,uu}$) were significantly lower, ranging from 0.06 to 3.4. This indicated that nonspecific binding is a significant component of the total B/P parameter.

A high value of total B/P may mislead CNS researchers into the believing that a drug is being actively taken up into the brain and reaching high brain exposure levels, while, in reality, total B/P is merely driven by the different binding in plasma and brain, as indicated by fraction unbound in plasma ($f_{u,plasma}$) and fraction unbound in brain ($f_{u,brain}$).

Theoretically, free B/P would not exceed 1.0 when no active influx transporters are involved. Therefore, in CNS drug discovery, it is prudent to use the free B/P as the parameter to assess the extent of brain penetration, to avoid driving medicinal chemistry efforts down fruitless path of changing nonspecific binding. The free B/P represents the net extent of drug penetration across the BBB, which includes the effects of transporters, without being confounded by unspecific binding [1]. Therefore, free B/P is a better parameter to measure the extent of brain penetration compared with total B/P.

The rate of brain penetration is important for CNS drugs that require rapid onset. It is important to recognize that the rate of drug entering the brain across the BBB is not equal to the extent of transport/distribution to the brain, as the rate determines how fast the drug enters brain, not how much has entered at steady state. Rate across BBB affects whether distribution equilibrium among the various compartments can be established quickly. Rate is determined by permeability of the BBB, which is the composite of passive diffusion, efflux transport, and influx transport. The more permeable the BBB is to the drug, the quicker the drug will reach the brain tissue, but it is not permeability alone that is important regarding drug delivery to the brain. The brain PK of a centrally acting drug, and thereby its associated PD, are the result of a combination of influx and efflux processes and the extent of distribution of the drug within the brain tissue.

Another important parameter is unbound volume of brain ($V_{u,brain}$). $V_{u,brain}$ describes the relationship between the total drug concentration in the brain and the unbound drug concentration in brain ISF. It is a useful measure of drug distribution in the brain parenchyma. $V_{u,brain}$ is the ratio of total drug concentration in the brain and the unbound drug concentration in brain ISF. Since brain ISF concentration is often

converted from total brain concentration and fraction unbound of brain tissue ($f_{u, \text{brain}}$). $F_{u, \text{brain}}$ is inversely proportional to $V_{u, \text{brain}}$ [1].

17.3 METHODOLOGIES IN ASSESSING BRAIN PENETRATION

17.3.1 *In Vivo* Approaches

17.3.1.1 Preclinical Neuro PK Studies. On the basis of the understanding of multiple brain compartments, as discussed above, and the importance of nonspecific binding in the brain, efficient *in vivo* neuroPK (neuropharmacokinetics) (i.e., brain PK) studies are conducted in animals as part of CNS drug discovery [4,7]. NeuroPK helps define the relationships between drug concentrations in the CNS compartments and understand the mechanism-based pharmacology, the exposure (PK) and response (PD) relationships. The species selected for neuroPK is based on the species used for efficacy and toxicology studies. Plasma, brain, and CSF are collected to assess drug distribution in the various compartments. The neuroPK information provides temporal brain intercompartmental compound concentrations to guide dose and time point selection for pharmacology studies in preclinical species. Even though neuroPK studies may employ any dosing route, subcutaneous administration is the most preferred approach since it bypasses first-pass liver metabolism and has low experimental variability. Occasionally, for compounds with intrinsically low rates of CNS penetration, significant delay in reaching distribution steady state may be of concern, in which case an intravenous infusion regimen can be applied [8]. In a typical rodent neuroPK study, animals ($N = 3/\text{time point}$, preferably at least two dose levels, for example, 1 and 10 mg/kg) are euthanized at specific time points post dose, and plasma, CSF, and brain are collected for exposure analysis. Time-concentration profiles of the compound in plasma, CSF, and brain are generated.

These data reveal important PK parameters providing insight into the extent of compound CNS penetration and rate of elimination from each compartment. Knowing matrix-specific diffusion and elimination rates is important as compounds may have intercompartmental concentration-related delays and/or much longer half-lives in brain versus CSF or plasma. Such phenomena are key to understand the mechanism of hysteresis observed in exposure-PD response. Furthermore, free drug exposures in each of the compartment, plasma, CSF, and brain, can be calculated by combining area under the curve (AUC)-derived exposures for each neuromatrix and compound-specific $f_{u, \text{plasma}}$ and $f_{u, \text{brain}}$ values, determined by equilibrium dialysis studies using plasma and brain homogenate, respectively (Eqs. 17.1 and 17.2). Under normal physiological condition, CSF is low in protein. Therefore, the concentration measured in CSF is, in general, considered approximately free drug concentration:

$$\text{Free drug exposures in plasma: } AUC_{p,u} = AUC_p \cdot f_{u, \text{plasma}} \quad (17.1)$$

$$\text{Free drug exposure in brain: } AUC_{b,u} = AUC_b \cdot f_{u, \text{brain}} \quad (17.2)$$

Ratios between $AUC_{p,u}$, AUC_{CSF} , and $AUC_{b,u}$ provide important insights into the extent of compound distribution among these brain compartments. The ratio of $AUC_{b,u}:AUC_{p,u}$, presuming $C_{b,u}$ and C_{ISF} are equivalent, provides the concentration relationship across the BBB. The ratio of $AUC_{\text{CSF}}:AUC_{p,u}$, on the other hand, gives an

TABLE 17.1 Methodologies in Predicting Free Human Brain Concentration

Methods	Description	Comments
Human receptor occupancy (RO)	$RO = C_{bu}/(C_{bu} + K_i)$	Human RO can be obtained from imaging studies (e.g., PET)
Human CSF	Sampling CSF in human	CSF can overpredict free brain concentration for efflux transporter substrates
Animal neuroPK and human unbound plasma	$C_{bu} = [C_{bu}/C_{pu}]_{rat} \times C_{pu}$	C_{bu}/C_{pu} is often preserved across species, except for sheep
Human unbound plasma	$C_{pu} = C_p \times f_{u,p}$	When distribution equilibrium is established, typically for high permeable compounds that are not efflux transporter substrates

idea of the extent of partitioning at the BCSFB. These two parameters are important in defining whether there is distribution equilibrium among these neurocompartments, which is critical in understanding preclinical efficacy and safety and in predicting brain penetration in human. Whereas, the ratio of $AUC_{b,u}:AUC_{CSF}$ defines the compound concentration relationship between ISF and CSF. This ratio is very important, particularly for a compound that demonstrated distribution disequilibrium at the BBB and/or at the BCSFB, because, for these compounds, plasma will overestimate drug exposure in brain ISF. If CSF exposure is determined in the clinic, human brain ISF exposure may be estimated from this using the rodent-derived relationship assuming an identical ratio across species (Table 17.1). For CNS compounds, careful characterization of these three exposure ratios increases the chances of adequate compound delivery to the pharmacologic target site and understanding cross-species exposure-response relationships.

17.3.1.2 CSF as a Surrogate for Brain Exposure. The use of CSF concentration as a surrogate marker for the unbound drug concentration in the CNS has become a more common practice for assessing CNS exposure. This is because there is a close relationship between the brain ISF and CSF, and CSF sampling is relatively simple and straightforward both in preclinical experiments and clinical settings. However, it is important to recognize, as aforementioned, that the brain consists of multiple compartments created by two distinct barriers (BBB and BCSFB) and that many factors are involved in the transport of drugs from plasma into the brain and the distribution within the brain. Systemically administered drugs can reach CSF either directly via passage across the BCSFB or indirectly by passage across the BBB followed by diffusion/convection transport from the ISF to CSF. Therefore, the usefulness of CSF as a surrogate for measurement of unbound drug concentration in the brain has been critically questioned [9]. From the PK/PD perspective, to determine whether CSF can serve as a surrogate for assessing the drug exposure at the pharmacological target site within the CNS and the dynamics of drug concentration–effect relationship, the critical issue is whether CSF concentration is in equilibrium with the target biophase concentration.

CSF, an essentially aqueous fluid free of drug binding proteins, circulates throughout the ventricles within the brain and the subarachnoid space surrounding the brain and

spinal cord. Because of its physically close proximity to the brain, drug concentration in the CSF is sometimes used as a surrogate of free drug concentration in the brain [10]. However, there are several important aspects of CSF worth special consideration when interpreting drug concentration in CSF as a surrogate exposure at the CNS target site.

First, drug distribution in CSF may be uneven, because CSF is not a well-stirred compartment. Unlike systemic circulation, where it takes <1 min to circulate blood throughout the body, the movement of CSF is much slower. The turnover rate of CSF is about 5–7 h. Drug concentration in CSF is expected to be significantly different depending on the site of CSF sampling and the route of administration. Remarkable differences (approximately 10-fold) in drug concentrations between ventricular and spinal CSF have been reported after intraventricular or lumbar injection [10]. The apparent differences in CSF drug kinetics between the ventricular and lumbar sites is not a surprise when one considers that the flow through the subarachnoid space receives only a fraction of the CSF flow originating from the ventricles. Furthermore, exchange of drug between CSF and the cord tissue bordering the descending spinal subarachnoid space probably exerts influence on the composition of the spinal CSF. These considerations definitely raise a serious question as to the usefulness of lumbar CSF as an indicator of drug availability and disposition in the brain.

Second, drug concentration in CSF is influenced by BCSFB at CP as well as drug concentration in ISF. The total volume of the CSF in adult humans is approximately 150–200 mL [11]. Various studies have suggested that about two-thirds of CSF is formed at the CP, and one-third of CSF enters the macroscopic spaces from brain ISF [12]. The BCSFB, separating blood from CSF, is formed by the epithelial cells of CP and their tight junctions. Unlike the BBB, the capillaries supplying the CP are fenestrated. Similar to the BBB, a number of influx and efflux transporters have been identified at the BCSFB. However, their locations and functions are somewhat different than those at BBB [13]. It has been reported that P-gp (MDR1 and ABCB1) localizes subapically at the CP epithelium, with drug transport in the direction from blood to CSF. In contrast, at the BBB, P-gp localizes at the luminal membrane of brain endothelial cells and pumps drugs out of brain. At BCSFB, other efflux transporters localize and function differently as well. Several groups of researchers showed MRP1 (ABCC1) localized basolaterally, conferring an opposing basolateral-to-apical drug-transport barrier. The localization of MRP1 suggests that MRP1 is an efflux transporter pumping drugs out of the CP, which is functionally different from P-gp at BCSFB. Understanding of the role of the BCSFB in transporting drugs into the brain is emerging and has been gradually gaining more attention over the years.

Despite the complexity of CSF physiology and PK, CSF sampling remains an important part of neuroPK study, which is a valuable tool for assessing drug CNS penetration in preclinical studies, and more importantly, projecting human CNS penetration (Table 17.1). Since CSF is not a homogeneous fluid, it is recommended that, in animal studies, CSF sampling be performed through a catheter inserted into the cisterna magna (in close proximity to the brain). In addition, drug distribution into CSF may be delayed from plasma due to low membrane permeability. Comparison of CSF and corresponding plasma unbound drug concentration based only on a single time point could be misleading. Therefore, it is highly desirable to assess CNS exposure in animals by comparing the AUCs of unbound drug concentration in CSF, brain, and plasma. As mentioned in the previous section, a well-conducted preclinical neuroPK

study will define drug distribution kinetics among CNS compartments and provide insights in designing a clinical study to assess human brain exposure. For compounds that exhibited distribution equilibrium among neurocompartments, free drug concentration in plasma can be used as a surrogate for brain exposure. For those that exhibited impaired brain penetration, CSF can be used as surrogate of drug brain concentration, as plasma will overestimate free drug exposures in brain. However, it is prudent to assess unbound drug concentration in the brain and use the ratio of $AUC_{b,u}:AUC_{CSF}$ to define the relationship between ISF and CSF, as equilibrium may not always be established between these neurocompartments.

In summary, CSF drug concentration can be used as a useful surrogate for assessing unbound drug concentration at the target site within the brain. However, CSF drug concentration is not always an accurate surrogate for all drugs, especially for transporter substrates. Preclinical neuroPK can be used to design clinical studies to assess CNS target exposure in humans (Table 17.1).

17.3.1.3 Microdialysis. According to the free drug hypothesis, unbound drug in brain ISF is in direct contact or in equilibrium with that at the site of action [2]. *In vivo* intracerebral microdialysis is a valuable technique to determine biophase free drug concentrations and distribution in the brain as a function of time. The technique involves implantation of a thin dialysis probe into a selected area of the brain. The probe consists of an inlet tube, a semipermeable membrane, and an outlet tube. To mimic the function of a capillary blood vessel, the thin dialysis probe is continuously perfused with an artificial physiological solution. Drug molecules diffuse across the membrane along the concentration gradient (in the direction of the lower concentration) into or out of the selected tissue. A basic principle of microdialysis is that only unbound drug can freely diffuse through the semipermeable membrane [14]. Depending on the physicochemical properties of the drug, the concentration measured with the probe may not reflect the concentration in the ISF but is a function of the probe perfusion rate, blood flow, and diffusion in the tissue surrounding the probe. Therefore, *in vivo* recovery of the probe for a specific compound will need to be incorporated to translate the concentration measured in the dialysate to the unbound drug concentration in the tissue [15].

Microdialysis has been used to monitor biophase concentrations of antiepileptic drugs in animals and humans. Walker *et al.* [16] investigated the rate of lamotrigine penetration into plasma, CSF, and hippocampal and frontal cortex extracellular fluid compartments following systemic administration in nonepileptic rats. Following intraperitoneal injection, the ISF AUC of lamotrigine to total serum AUC ratio (0.4 ± 0.01) was similar to the free serum AUC to total serum AUC ratio (0.39 ± 0.01), and did not differ between hippocampus and frontal cortex. On the other hand, the CSF AUC to total serum concentration AUC ratio was 0.6 ± 0.05 . Overall, the unbound concentrations of lamotrigine in three different compartments, serum, CSF, and ISF, were in a reasonably good agreement, supporting the concept of free drug hypothesis. In human, an intracerebral microdialysis study was also conducted during surgery by Scheyer *et al.* [17], who collected dialysate from the hippocampus of refractory epilepsy patients and determined phenytoin level in the dialysate. The steady-state extracellular phenytoin concentrations corresponded closely to the unbound plasma concentration, indicating free drug distribution equilibrium between brain ISF and plasma.

Although the microdialysis technique was developed more than two decades ago, it is primarily used for determination of neurotransmitters and not drug concentrations in the brain in the pharmaceutical industry. The main limitations of this technique include high resource requirements, low throughput, and special surgical skills to set up the experiment. In addition, many compounds in the discovery stage are very lipophilic, and it is difficult to apply microdialysis technique to study these compounds because of high nonspecific binding to the dialysis devices and tubing. Importantly, this method cannot be used routinely to measure the ISF concentration in the clinic for ethical reasons. Because of these constraints, alternative methods, such as CSF sampling and neuroPK studies combined with brain homogenate binding, have been used to estimate brain ISF exposure. The accuracy of using unbound brain concentration determined by a neuroPK/brain homogenate binding method and CSF exposure as a surrogate for brain ISF concentration was compared with those obtained by microdialysis in rat brain [8]. The results supported the use of neuroPK/brain homogenate approach or CSF as a surrogate for the ISF free drug concentration in drug discovery and also confirmed the distribution disequilibrium between brain, CSF, and plasma for efflux transporter substrates and low permeability drugs.

17.3.1.4 PET Imaging. Imaging is an attractive technique to obtain information on brain drug uptake in humans due to the noninvasive nature of the approach. There are a number of methods for imaging compounds in the brain, including positron emission tomography (PET), single photon emission computed tomography (SPECT), and magnetic resonance imaging (MRI). Before PET and SPECT, MRI was used to obtain PK information of drug in brain [18]. It suffered from low spatial resolution; therefore, its value for quantitative assessment was limited. PET and SPECT both use radioactive tracer materials and detect γ -rays. However, the tracer used in SPECT emits γ -radiation that is measured directly, whereas PET tracer emits positrons that annihilate with electrons up to a few millimeters away, causing two γ -photons to be emitted in opposite directions. A PET scanner detects these emissions “coincident” in time, which provides more localized information of radiation events and higher resolution images than SPECT. Therefore, PET is a better quantitative method for assessing drug brain distribution. SPECT scans, however, are significantly less expensive than PET scans, in part because they are able to use longer lived more easily obtained radioisotopes than PET. PET is a nuclear medicine imaging technique that produces a three-dimensional image or picture of functional processes in the body. The system detects pairs of γ -rays emitted indirectly by a positron-emitting isotopes (^{11}C , ^{13}N , ^{15}O , or ^{18}F), which is incorporated into the drug of interest. Typically, the isotopes are made in a cyclotron, and because of their short half-lives, they need to be rapidly incorporated into drug immediately before administration. Once administered to a patient, the label can be imaged noninvasively using a PET scanner. To study drug brain distribution, there are two main approaches using PET. The first is the direct approach, where the drug itself is labeled. The second is the indirect approach, where a labeled receptor ligand is administered and then unlabeled drug of interest is administered. The time course of receptor occupancy will be measured using the PET scanner as the drug displaces the ligand from the receptor.

Verapamil, a calcium channel blocker, has been used as a PET tracer to assess P-gp-mediated transport at the BBB in human, since it is a P-gp substrate and can also be straightforwardly labeled with ^{11}C . A human volunteer study utilizing [^{11}C]-verapamil

as a model P-gp substrate and cyclosporine A (CsA) as a P-gp inhibitor was conducted by Sasongko *et al.* [19]. Results showed that the inhibition of P-gp activity at the human BBB was modest, with $\sim 90\%$ increase in [^{11}C]-verapamil distribution into the brain in the presence of $\sim 2.9\ \mu\text{M}$ steady-state blood CsA concentration. These results are dramatically different from those obtained in the P-gp knockout (KO) or chemical KO mouse or in rats administered with a high dose (e.g., 50 mg/kg) of CsA, where ~ 10 -fold increase in [^{11}C]-verapamil distribution into the brain was observed when compared with the wild-type mouse [20]. The observed discrepancy in the verapamil–CsA interaction at the BBB between rodents and human is likely due to differences in blood CsA concentrations. The PET imaging study provided evidence for the first time that P-gp activity at the human BBB is measurable and that it is only modestly inhibited by one of the most potent and Food and Drug Administration-approved P-gp inhibitors, cyclosporine. Kinetics of drug brain uptake must be interpreted with reference to concurrent blood drug concentrations and it is difficult to define the blood kinetics of a compound using PET alone. Solid-phase extraction (SPE) and high performance liquid chromatography (HPLC) analysis was used to determine the amount of radioactive verapamil and its metabolites in the plasma [19]. However, for a drug such as verapamil, which has a $t_{1/2}$ in the range of 6–8 h, the plasma concentration–time profile of ^{11}C -labeled parent tracer would fail to predict the drug's PK parameters as the drug's elimination phase cannot be captured during the short time course of the PET experiment. For such drugs, a combination of PET imaging for assessment of drug tissue distribution with accelerator mass spectrometry (AMS) for plasma PK analysis can be particularly powerful. Verapamil brain distribution kinetics was determined in human in a microdosing study combined with PK profiling in plasma using AMS after administration of a mixture of (*R*)-[^{11}C]verapamil and (*R/S*)-[^{14}C]verapamil [21]. Each subject underwent PET scan of 60-min duration after receiving a microdose of labeled verapamil. The time–concentration profile of (*R*)-verapamil in human brain was demonstrated by reconstruction of the PET data, while concentration in plasma was profiled using HPLC with a radiometric detector, chromatographically separating parent drug and metabolites.

PET imaging also provided the opportunity to study species difference of P-gp transporter at the BBB by measuring brain concentrations and brain-to-plasma ratio of three labeled P-gp substrates, [^{11}C]verapamil, [^{11}C]GR205171, and [^{18}F]altanserin in rats, guinea pigs, monkeys, and humans [22]. Pronounced species differences were found in the brain and brain-to-plasma concentrations of these P-gp substrates, with higher brain distribution in humans, monkeys, and minipigs than in rats and guinea pigs. The brain-to-plasma ratio of [^{11}C]GR205171 was almost ninefold higher in humans compared with rats. These findings suggested species differences should be considered when extrapolating data obtained in animals to humans. Compounds found to be P-gp substrates in rodents are likely to be substrates in higher species as well, but the ratio of brain penetration, even corrected with binding factors, may not be reliably extrapolated from animals to humans. Despite these reported species differences, an in-depth study has revealed that the rodent is a suitable model for CNS penetration (Section 17.4.1).

The advantages of PET are obvious as it is not only noninvasive, which makes it attractive for clinical applications, but it also allows drug concentrations and/or receptor occupancy to be followed with high spatial (several millimeters) and time resolution. Thus, it is possible to monitor drug concentrations or effects in discrete structures in the brain. However, on a practical level, a disadvantage of PET is that it requires expensive

infrastructure (i.e., both a cyclotron and PET scanner in close proximity). PET also requires clever chemistry (i.e., dedicated personnel) to incorporate labels rapidly into compounds of interest before the label has decayed excessively. The other limitation of PET is that, in general, it is unable to discriminate between bound and unbound drug or parent compound and metabolites. Because of these reasons, there has been less use of PET for animal studies during the discovery stage, but there is now a growing trend for its use in drug development with the availability of commercial small animal PET scanners [23].

17.3.2 *In vitro* Methods

17.3.2.1 BBB Permeability. Passive permeability is an important parameter for assessing the rate of CNS penetration, since most small molecules enter the brain by transcellular passive diffusion. The rate of brain penetration plays a critical role for drug candidates that require rapid onset of pharmacological effects (e.g., anesthesia). It is also pivotal in terms of time necessary to achieve distribution equilibrium among the various neurocompartments (e.g., brain, CSF, and plasma).

In situ brain perfusion is the gold standard method for measuring BBB permeability *in vivo* [24,25], since it is quite reliable to determine the rate of brain penetration. In the brain perfusion studies, animals were anesthetized. The test compounds were infused in a perfusate to the external carotid artery for about 30 s [26]. At the end of the experiment, animals were sacrificed and the brains were homogenized and analyzed with liquid chromatography–mass spectrometry (LC-MS). Although it is useful, the *in situ* brain perfusion assay is not commonly applied in the pharmaceutical industry, because it does not provide the free drug concentration in the brain directly, which is most important for pharmacological activity. Instead, *in vitro* BBB permeability assays or calculated properties are more frequently employed to estimate the rate of brain penetration. There are two major *in vitro* BBB permeability methods: (i) parallel artificial membrane permeability assays (PAMPA-BBB) and (b) cell-based monolayer permeability assays [e.g., MDCK apparent permeability (P_{app}) from apical to basolateral].

PAMPA is a high throughput assay for passive diffusion originally developed to mimic intestinal membrane permeation and predict oral absorption [27–29]. The assay was further expanded to predict BBB permeability (PAMPA-BBB) using brain lipids as the artificial membrane [30,31]. PAMPA-BBB permeability values correlated well with *in situ* BBB permeation values obtained from brain perfusion experiments in rodents [32,33]. Because PAMPA-BBB has good predictability of the rate of brain penetration and is high throughput with low cost, it is a valuable tool as first-tier screening in drug discovery for BBB permeability.

Cell monolayer transport assays with primary cells or cell lines are also commonly used as models to assess BBB permeability, such as MDCK, LLC-PK1, Caco-2, and brain microendothelial cell (BMEC) [34]. Among the various cell-based *in vitro* assays, MDCK cells are most commonly used [26,34–36] to predict BBB permeability. Although MDCK cells are not of cerebral origin, the MDCK permeability assay has clear advantages over other cell types: easy cell culture, low maintenance, tight cellular junctions, low endogenous transporters, and low metabolizing enzymes. Recently, a

MDCK-LE (low efflux) cell line has been developed to further minimize the potential interferences from endogenous transporters on passive permeability measurement [37].

A comparison study on PAMPA and MDCK was conducted using 31 structurally diverse marketed CNS-active drugs, one active metabolite, and seven non-CNS-active compounds [38]. In general, the two assays gave a good correlation. Compounds with $P_{app} > 5 \times 10^{-6}$ cm/s in PAMPA or MDCK had a good BBB permeability *in vivo*. Importantly, most successful marketed CNS drugs have moderate to high passive permeability. Additionally, *in silico* models have been quite successful in predicting passive permeability across the BBB based on molecular properties and they can be applied effectively in early drug discovery [39,40].

17.3.2.2 Brain Tissue Binding. As discussed above, free drug concentration at the site of action is the species that exerts pharmacological activity and the free brain/plasma ratio ($C_{b,u}/C_{p,u}$) is an important parameter to evaluate the brain penetration potential of drug candidates. Several methods have been developed to measure free brain concentration, including microdialysis, CSF sampling, and a combination of neuroPK and brain tissue binding (Section 17.3.1). In drug discovery and development, it is a common approach to obtain free drug concentration in the brain by a combination of neuroPK and brain tissue binding studies, and the free C_{max} and AUC are obtained using Equation 17.2. The approach has been shown to have a good correlation with direct microdialysis and indirect CSF measurements in determining free drug concentration in the brain *in vivo* [5,41,42].

There are two methods that are commonly used for brain tissue binding measurements, which use (i) brain slice [41,43–45] or (ii) brain homogenate [46–49]. Brain slices preserve the cellular structures (cell membrane, influx and efflux transporters, and ICFs) and are considered physiologically more relevant. However, even with the difference between brain slice and brain homogenate, the two methods have a good correlation in measuring f_u values, especially when cytosolic pH partition is corrected for basic compounds [44,50]. It appears that the nonspecific binding to lipophilic components in the brain is the dominant mechanism for brain tissue binding, and that the presence of intact structural elements plays a less significant role in determining brain binding. One advantage of using brain homogenates over brain slices is that they are readily available from vendors and can be stored frozen and thawed right before experiments. High throughput 96-well format dialysis devices have been developed and can be used to determine f_u using brain homogenates (e.g., HTD 96 from HTDialysis [51] and RED from Thermo [52]). The devices are engineered to minimize nonspecific binding to the plastic wells and dialysis membranes to shorten the time required for compounds to reach equilibrium. The advantage of the equilibrium dialysis device is that nonspecific binding does not affect f_u determination, which is particularly important for highly lipophilic compounds. The good predictability of *in vivo* free drug concentration and the ease of use make brain homogenate binding one of the most widely employed methods for determining fraction unbound in brain tissue. While plasma protein binding is often species dependent, brain tissue binding has been shown to be species independent [53]. One can use a single species (e.g., rat) to estimate brain binding of all other species, including human in drug discovery. This greatly increases efficiency and reduces cost. Brain tissue binding has been shown to be independent of regional brain tissues [54], and the brain regions in the study included

CP, striatum, hippocampus, motor cortex, cerebellum, and thalamus [54], suggesting that no regional brain binding studies are necessary.

There are many misconceptions among drug discovery project teams regarding drug binding *in vivo*, including the perceived value of increasing fraction unbound through structure modification [2]. The rational of this misconception is to increase the free drug concentration at the site of action by manipulating fraction unbound. This approach is scientifically unsound. Changing fraction unbound will not affect free drug concentration *in vivo* for orally administrated drugs. Project teams should not attempt to increase fraction unbound to improve free drug exposure at the target or use fraction unbound to rank order compounds. Fraction unbound should only be used to calculate the free drug concentration by multiplying it to the total drug concentration obtained from *in vivo* neuroPK studies. For this reason, f_u data alone can be misleading and one does not need to measure f_u , unless *in vivo* total drug concentration or AUC exposure data has been measured.

17.3.2.3 Transporters. Measurement of the interaction of drugs with BBB transporters is critical in predicting the brain penetration potential of drug candidates. Many influx (solute carrier) and efflux (ATP-binding cassette, ABC) drug transporters in the BBB (Fig. 17.2) and the BCSFB have been reported [55]. More than 200 drug transporters in human BMECs were profiled using real-time polymerase chain reaction (PCR) [56]. The expression of human P-gp (MDR1, ABCB1) and breast cancer resistance protein (BCRP, ABCG2) are the highest in human BBB based on mRNA level [56]. Recently, 114 drug transporter protein levels were quantitatively determined in human brain microvessels using proteomics approaches with LC-MS/MS. The results showed that human P-gp and BCRP are the most abundant transporter proteins at the BBB, which is consistent with the mRNA levels [57]. On the basis of the protein level, human BCRP is slightly higher than P-gp in brain microvessels in the ratio of about 4:3. The human BCRP protein level is higher than mouse Bcrp, while human P-gp is lower than mouse P-gp in the BBB [57]. Transporter protein levels have also been reported for monkey with P-gp and Bcrp being the two major transporters in

Figure 17.2 Drug transporters expressed at human blood–brain barrier.

the BBB. Monkey has slightly higher amounts of Bcrp compared with human [58]. Though human BBB BCRP has a slightly higher amount than P-gp, P-gp has been the dominant efflux transporter at the BBB to reduce compounds from entering the brain. P-gp and BCRP have a large substrate overlap and many BCRP substrates are P-gp substrates, and only a small number of compounds are BCRP-specific substrates. This may account for why P-gp seems to play a more important role than BCRP in limiting brain penetration of drugs *in vivo*. P-gp and BCRP transporters have a synergistic effect in restricting their dual substrates from entry into the brain, which is expected based on individual kinetic contribution to BBB efflux [59–62]. This has been applied in designing drugs that target peripheral tissues, where brain penetration can cause unwanted side effects. Besides P-gp and BCRP, other efflux transporters, such as MRP4, can pump certain compounds out of brain. However, the *in vivo* significance of other efflux transporters in the BBB is not well defined. Uptake transporters at the BBB, such as OATP1A2, OATP2B1, LAT1, and MCT1, can enhance transport of some drugs into the brain. L-DOPA, gabapentin, and pregabalin are examples of drugs that are active influxed into the brain by the LAT1 transporter [63]. It has been reported recently that OATP1A2 is a potential transporter to increase active uptake of certain drug candidates into the brain [64]. A positively charged amine atom is required for efficient OATP1A2-mediated uptake, and the uptake rate is in the order of tertiary > secondary > primary amines [64]. Uptake rate also improved with increased van der Waals volume, but not with Clog *P* [64]. The *in vivo* relevance of OATP1A2 in enhancing the CNS penetration has yet to be demonstrated.

Several *in vitro* BBB models with primary brain endothelial cells or immortalized brain endothelial cells have been developed. These models tend to have leaky junctions between the cells and downregulation of BBB transporters. Although they are of brain endothelial cell origin, the leaky junctions, low transporter expression, and high cost make them unsuitable for use on regular bases to support of drug discovery programs. Instead, the most common approach to assess transporter substrates and inhibitors is to use transfected cell lines that express selected transporters, for example, MDR1-MDCK, BCRP-MDCK, OATP1A2-HEK, and others. Cutoff values are established to differentiate substrates from nonsubstrates, typically based on empirical evaluation of compounds with known substrate properties. *In vitro* transporter data based on cell monolayer transport studies have a good correlation with *in vivo* results from transgenic animals. A study on P-gp efflux for a set of structurally diverse drugs showed that MDR1-MDCK data had a good correlation with *in vivo* efflux ratio obtained from P-gp KO mice versus wild type [6,38]. P-gp efflux activity is usually conserved across various species due to a high sequence homology of the protein (80–96%, rat, mouse, dog, and monkey). More than 3000 compounds were tested at both human MDR1-MDCK and mouse Mdr1a-MDCK transwell assays *in vitro*, and a good correlation ($R^2 = 0.92$) of efflux ratios was observed [38]. However, for certain structural classes, species difference in P-gp efflux has been demonstrated [65]. Cell lines transfected with transporters (e.g., P-gp and BCRP) from various animal species can be used to evaluate the different transporter activities from the different species. Human MDR1-MDCK showed to have a better prediction of human P-gp effect on BBB penetration than using P-gp KO mice, due to its human origin and high sensitivity without added complexity from various *in vivo* factors. Though the value of P-gp KO is to understand whether P-gp plays a major role in limiting brain penetration in mouse has been demonstrated, its predictive value to human P-gp interaction is limited compared with transfected

cell lines with human origin. Transporter information is widely used by project teams to guide structural modification, develop SAR (Structure-Activity Relationship), select compounds for *in vivo* studies, and diagnose *in vivo* observation.

P-gp found at the BBB reduces entry of toxic materials into the brain. Impaired P-gp function due to generic polymorphism, disease state, or aging may raise the levels of toxic compounds in the brain and increase the risk of developing certain neurodegenerative diseases. For example, decreased expression of P-gp in the BBB vasculature has been found in patients with advanced Parkinson's disease [66], Alzheimer's disease [67], and Creutzfeldt–Jakob disease [68]. In AD, P-gp upregulation in early pathogenesis was suggested as a compensatory mechanism to increase the capacity of detoxification, while at later disease stages, P-gp expression was lost due to brain cell degeneration [67]. Decreased BBB P-gp function seems to be a late event in neurodegenerative disorders and could enhance continuous neurodegeneration [66]. On the other hand, P-gp activity was found to increase in patients with chronic schizophrenia under treatment with antipsychotic drugs. The increased P-gp activity might be a factor for drug resistance in schizophrenia, induced by the use of antipsychotic agents [69]. Additionally, P-gp activity at certain BBB regions decreased during aging, which increased the risk of developing brain diseases [70,71].

17.3.3 *In Silico* Predictions and Simulations

17.3.3.1 Computational Models. A number of CNS models have been developed to predict brain penetration and they are most useful for library design and prediction before synthesis [72,73]. Models predicting passive permeability across the BBB have been developed using molecular descriptors related to lipophilicity, hydrogen bonding capacity, charge, and molecular weight (MW) [74], as well as descriptors [39], such as $\log D$, van der Waals surface area of basic atoms, and polar surface area (PSA). Models for active or facilitative transporter processes are less mature owing to insufficient quality data necessary for model development. The rules for good CNS penetration are $\text{PSA} < 60\text{--}70 \text{ \AA}^2$, $\log D$ between 1 and 3, and $\text{MW} < 450$, and rules for non-Pgp substrates are $\text{N} + \text{O} \leq 4$, $\text{MW} < 400$, and $\text{base } \text{p}K_a < 8$ [75–77].

17.3.3.2 CNS Multiparameter Optimization. To increase the survivability of CNS drug candidates, multiparameter optimization (MPO) was developed to shift the neuroscience medicinal chemistry to a design space with a higher probability of success [78]. Six calculated parameters were utilized to understand the interplay among the different physicochemical properties and to create a design tool focusing on aligning the CNS drug-like attributes. The six parameters in CNS MPO are lipophilicity ($\text{Clog } P$), distribution coefficient at pH 7.4 ($\text{Clog } D$), MW, topological polar surface area (TPSA), number of hydrogen bond donors (HBD), and basicity of the most basic center ($\text{p}K_a$) [79]. The CNS MPO scoring function offers great advantages over simple hard cutoff rules or using single parameter for optimization. The CNS MPO enables exploring medicinal chemistry design space through a holistic assessment approach to accelerate the identification of compounds with increased probability of success [80].

17.3.3.3 PBPK Models for BBB. Physiologically based pharmacokinetic (PBPK) models for BBB are based on the anatomical and physiological structure of the body and certain biochemistry. They are powerful tools to quantitatively predict brain exposure time course, brain-to-plasma ratio, and other important PK parameters *in vivo* [81]. Commercial BBB PBPK software is recently made available [82]. One of the challenges facing BBB PBPK models is to integrate transporter activity into the prediction. Several human BBB transporter proteins have been quantified using LC-MS [57]. The information, in conjunction with the level of transporter proteins in transfected cell lines, can provide a scaling factor to predict CNS penetration effectively.

Recently, *in vivo* disposition of 11 P-gp substrates in mouse brain was predicted using a PBPK model that incorporated the P-gp protein level in mouse brain capillaries and in transfected cells, P-gp *in vitro* activity, and drug unbound fractions in mouse plasma and brain [83]. For most of the compounds, the predicted brain-to-plasma concentration ratios and unbound brain-to-plasma concentration ratios were within three-fold of the observed *in vivo* values. With the progress in transporter proteomics in human BBB, the brain distributions of P-gp substrates in human would be predicted from the P-gp protein levels, *in vitro* activity, and drug unbound fractions as well. However, it is a challenge to validate the accuracy of the model in predicting human brain disposition, since the unbound human brain concentration is often unknown, and CSF and CNS pharmacology activity is unlikely to be in equilibrium with the free brain concentrations due to transporter interactions. The advances in imaging technology (e.g., PET) will be very helpful to validate the BBB PBPK models in humans.

17.4 RETROANALYSIS FOR PFIZER CLINICAL CANDIDATES

For drugs that have a site of action within the CNS, brain penetration is essential in accessing the site of action to deliver their pharmacological benefits and having a balanced efficacy and safety profiles. Even though all drugs do penetrate brain to some extent, drugs that have impaired brain penetration will have reduced exposures in brain and require proportionally higher doses to achieve therapeutic exposure at the CNS target site. Therefore, within CNS drug discovery, it has been recognized that having “good” CNS penetration is an added requirement for selecting promising drug candidates. However, in contrast to the established approaches of predicting systemic human PK parameters [84], it is not so obvious how to predict whether a compound will exhibit good CNS penetration in human.

Multiple factors contribute to the uncertainty around predicting human CNS penetration. First, how to measure brain penetration in human has always been a challenge. The easily accessible measurement site, blood, does not always reflect brain exposure. Despite close proximity of CSF to the brain, the value of CSF can be limited in predicting the drug concentration at the target site biophase in the CNS [12] (see above discussions). Intracerebral microdialysis and PET imaging are much improved techniques; however, their applications in CNS drug discovery and development are limited as intracerebral microdialysis is highly invasive, while suitable radiolabeled PET ligand may not be readily available for the novel drug targets being pursued. Furthermore, the limited human CNS exposure data have greatly hindered the progression

of predicting human CNS penetration, because multiple iterations of prediction refinement is the only way to advance predictive ADME science, as evidenced by success in the area of human PK prediction [85].

Nevertheless, the pharmaceutical industry has invested a significant amount of research in understanding factors influencing CNS drug disposition and, subsequently, in developing comprehensive tools to select candidates that have the best potential of being developed as successful CNS drugs. The preclinical tool box encompasses *in vitro* assays (e.g., membrane permeability, P-gp efflux transporter using MDR1-MDCK, and many others are being developed) and *in vivo* assays (e.g., neuroPK in rats, dog model for CSF sampling, and P-gp KO mouse). These are routinely used for CNS drug candidate selection. Questions have been raised regarding the predictability of these assays and confidence in using preclinical information in prediction of CNS penetration in humans. A retrospective analysis was conducted using 32 Pfizer proprietary clinical candidates, mostly with CNS indications, to address these important questions.

17.4.1 Preclinical and Clinical Data Used for Retrospective Analysis

To enable retrospective analysis, 32 Pfizer clinical candidates were selected that had either (i) CSF drug concentrations measured in humans or (ii) free drug concentrations in brain derived using receptor occupancy (from humans who had undergone clinical PET imaging studies), as well as *in vitro* receptor binding affinity, K_i . These 32 clinical candidates covered a wide range of CNS targets, including transmembrane G-protein-coupled receptors (GPCR), neurotransmitter gated channels, and ion channels. Their preclinical *in vitro* and *in vivo* data packages were collected, which included mainly membrane permeability, P-gp efflux, and brain penetration information from studies conducted in animals, mostly rats and mice, and a few guinea pigs or dogs. Compounds, which were shown as P-gp efflux substrates *in vitro* and/or exhibited brain penetration impairment *in vivo*, were also subjected to brain penetration studies in P-gp KO mice versus wild-type mice to confirm the role of P-gp in limiting their brain penetration [6].

These compounds were put into three groups (Fig. 17.3) based on their preclinical information by asking two questions: (i) Does the compound have a P-gp efflux liability and have low membrane permeability? (ii) Does the compound have good CNS penetration in animals? Since compounds in the data set are optimized clinical candidates, most of them have reasonably good membrane permeability. Therefore, the answer to the first question was essentially based on P-gp efflux liability. For the second question, free drug-based neuroPK methodology (see above) was applied to assess CNS penetration in animals. Compounds were considered as exhibiting interneurocompartamental distribution equilibrium when free drug exposures, in terms of AUC, were within 2.5-fold among plasma, CSF, and brain [5]. Compounds that showed both good *in vitro* and *in vivo* CNS penetration properties, meaning not having P-gp efflux liability and demonstrating good CNS penetration in animals, were categorized as group I compounds, also called *well-behaved* CNS compounds. On the other hand, compounds identified as having P-gp efflux liability and also preclinically showing impaired brain penetration were categorized as group III compounds. The remaining were put together as group II compounds, which had conflicting *in vitro* and *in vivo* findings, being either a P-gp efflux substrate or not showing distribution equilibrium among plasma, CSF, and brain compartments in preclinical species.

Figure 17.3 Road map of categorizing Pfizer proprietary clinical candidates ($n = 32$) into three groups based on their preclinical information. Group I (“well-behaved” CNS compounds): consistent *in vitro* and *in vivo* preclinical data suggesting good CNS penetration; group II: conflicting *in vitro* and *in vivo* preclinical CNS penetration data; and group III: consistent *in vitro* and *in vivo* preclinical indication impaired CNS penetration.

17.4.2 Human CNS Penetration Predicted from Preclinical Data

Human CNS penetration of these compounds revealed predictability of preclinical information (Fig. 17.4). For group I, or “well-behaved” CNS compounds, all of them exhibited good CNS penetration in human based on distribution equilibrium between CSF exposure and plasma or the fact that observed receptor occupancy could be predicted from unbound plasma in human and *in vitro* binding affinity. Furthermore, when

Figure 17.4 Correlation of preclinical and clinical CNS penetration of 32 Pfizer proprietary clinical candidates. Grouping was based on preclinical information (Fig. 17.3). Human CNS penetration assessment was based on human CSF/unbound plasma ratio using a cutoff of 2.5, human receptor occupancy data or efficacy outcome.

Figure 17.5 Correlation between $f_{u,\text{plasma}}$ and CSF/plasma ratio for group I compounds across multiple species. For compounds that exhibit free drug distribution equilibrium between CSF and plasma, unity line correlation is expected. The plot shows that majority of group I compounds are within 2.5 boundary of the unity line, indicating distribution equilibrium between CSF and plasma compartments.

plotting $f_{u,\text{plasma}}$ against the CSF/plasma ratio, essentially comparing CSF concentration with unbound plasma concentration, a majority of group I compound's data, across multiple species, are within the 2.5-fold boundary of the unity line (Fig. 17.5), indicating that for group I compounds, human CSF concentration data does not provide extra value over plasma free drug concentration data as a surrogate for CNS target exposure. This has a significant implication for CNS drug development, as this means for “well-behaved” CNS compounds, unbound plasma concentration is as good as CSF concentration in assessing PK/PD relationships at the CNS target site. Moreover, CSF sampling can be avoided, meaning significant clinical development cost saving and reducing unnecessary safety risk for clinical trial participants.

Group III compounds also had consistent *in vitro* data and *in vivo* preclinical CNS penetration data, with both data sets projecting unfavorable human CNS penetration. As expected, for these compounds, clinical data based on human CSF or receptor occupancy was consistent with preclinical prediction, all the group III compounds had impaired CNS penetration in human (Fig. 17.4). Furthermore, cross-species comparison of the CSF/unbound plasma concentration ratio indicated that a magnitude of disequilibrium between CSF and plasma compartments (i.e., CSF/unbound plasma ratio) is not consistent across species even when differences in plasma protein binding were accounted for. Though these compounds still penetrate brain, what makes their clinical development difficult is that it is very hard to get an accurate estimate of the actual concentration at the target biophase. As an example, one of the group III compounds, CP-615003, a potent subtype-selective GABA_A partial agonist, was once brought into clinical development as a psychotherapy, but discontinued due to lack of efficacy [86].

The compound was known to have P-gp efflux liability, and preclinical CNS penetration studies also indicated impaired brain penetration. Nevertheless, the compound was brought forward into clinical development, because it was believed that sufficient target receptor occupancy could still be achieved based on projected CSF exposure in human. However, clinical PET imaging clearly demonstrated an underachieved receptor occupancy in human. Intracerebral microdialysis in rats conducted afterward revealed that this is due to a further distribution gradient from CSF to ISF. For the mechanism of the drug, exposure in the ISF drove the downstream pharmacological effect. It was shown that there was a 43-fold difference in unbound drug exposure between ISF and plasma, compared with only an 8-fold difference between CSF and plasma.

Similar to the preclinical observations, human CNS penetration of group II compounds has mixed results (Fig. 17.4). The large percentage of compounds in group II in the data set (~44%) reflects the difficulty of evaluating and predicting CNS penetration. It was noted that possible species difference in P-gp efflux contributed to the different outcomes between preclinical and clinical CNS penetration [65]. Also, transporters, other than P-gp, were found to play a role in uptake or efflux of compounds into or out of brain, respectively (e.g., BCRP [55,57]). From a technical perspective, accuracy in determining extremely high nonspecific binding (>99.9%) may also confound result interpretation from preclinical neuroPK studies. On the clinical side, for compounds that exhibit delayed distribution kinetics among neurocompartments, single time point CSF sampling may not represent steady-state CNS penetration in human. These findings underscore the necessity of further research in the area of CNS drug disposition. Furthermore, it is important to understand the time course of drug disposition in CSF, and its relevance to target biophase, when designing clinical trials incorporating a CSF sampling end point for assessing CNS target exposure in human.

17.4.3 Predictability of Physicochemical Properties and Preclinical *In Vitro* and *In Vivo* Studies

The predictability of the four most commonly used preclinical assays, namely *in vitro* human P-gp, rat neuroPK, dog CSF PK, and P-gp KO mice studies, were evaluated, based on their correlation with human CNS penetration observed in the clinic (Fig. 17.7). Results indicated that all the human P-gp substrates from the analysis had impaired CNS penetration in human, confirming the critical role of P-gp efflux in drug CNS disposition. In contrast to the expectation that the dog CSF model is a better predictor for human CNS penetration than rat neuroPK, comparable human predictability was observed between the two models, suggesting rat neuroPK as the choice for efficient preclinical evaluation. Interestingly, P-gp KO mice had some “false positive” and some “false negative” prediction for human CNS penetration. These were found to be due mostly to species differences in P-gp efflux between human and mouse and to involvement of other efflux transporters, such as MRP4. Nevertheless, the P-gp KO mice study is still a useful tool to identify whether observed brain distribution impairment in rodents is primarily driven by P-gp.

Brain-penetrant CNS drugs are known to have certain physicochemical attributes [7]. Physicochemical properties of the 32 drug candidates were profiled and their correlations with human CNS penetration were sought (Fig. 17.6). Results confirmed that physicochemical properties, such as MW, lipophilicity (log *P* and log *D*), and PSA,

Figure 17.6 The roles of physicochemical properties and *in vitro* properties in predicting human CNS penetration. Clog *P*, Clog *D*, and PSA (polar surface area) were calculated using ACD Lab software (www.acdlabs.com). Passive permeability was assessed using a variant of MDCK cell line that does not express P-gp. MDR1 efflux ratio was obtained from transwell assay using MDR1-MDCK cell line.

are important determinants of CNS penetration. However, none of these should be used alone or as hard criteria when selecting CNS-penetrant compound (Section 17.3.3.2). One interesting observation is that the human P-gp assay appears to be the best assay to identify compounds that will have brain distribution impairment in human, as all the P-gp substrates in the data set exhibited distribution disequilibrium between plasma and brain/CSF ratios in human. However, the opposite is not true, as not being a P-gp substrate did not guarantee good CNS penetration in human (due to possible low passive permeability or efflux by other transporters).

17.4.4 Summary of Retroanalysis Results of Pfizer Proprietary Clinical Candidates

The outcome of retrospective analysis, wherein the predictability of preclinical assays for human CNS penetration was evaluated using 32 Pfizer proprietary clinical candidates, was encouraging (Fig. 17.7). When the human P-gp assay and rat neuroPK characterization (free drug partitioning between plasma, brain, and CSF) show consistent results, the two preclinical assays are effective in prediction of human CNS penetration with high confidence. When there is no human P-gp liability and good CNS penetration in rats (equilibrium of free drug partitioning between plasma, brain, and CSF), good CNS penetration in humans is predicted. More importantly, for

Figure 17.7 Predictability of preclinical assays to human CNS penetration, assessed by correlating results from human P-gp (MDR1/MDCK), P-gp KO mice model, rat neuroPK, and dog CSF model, respectively, to outcome of human CNS penetration observed in clinical trials by either human CSF exposure or receptor occupancy by PET. (a) Correlation of human P-gp and human CNS penetration, (b) correlation of KO mice and human CNS penetration, (c) correlation of rat and human CNS penetration, and (d) correlation of dog and human CNS penetration.

these compounds, the free drug exposure in plasma reflects the CNS target exposure in human. On the other hand, when there is human P-gp liability and impaired CNS penetration in rats (impaired drug partitioning between plasma, brain, and CSF), poor CNS penetration in humans is predicted. For these compounds, the free drug exposure in plasma will overestimate the CNS target exposure. In addition, the results of this retrospective analysis clearly underscore the need for further research in areas, such as transporters and brain PBPK, to better understand the physiological and molecular mechanisms influencing brain penetration and to predict human CNS penetration for compounds that exhibit less than favorable CNS penetration properties.

17.5 CONCLUSIONS

Integrated *in silico*, *in vitro*, and *in vivo* approaches have been developed to predict brain penetration of drug candidates. A BBB screening strategy is shown in Fig. 17.8

Figure 17.8 BBB screening paradigm in CNS drug discovery. *Source:* Modified from Ref. 3.

as an example to evaluate and predict brain exposure of drug discovery compounds. The key take-home messages and learning about BBB are summarized as follows:

- Use $K_{p,uu}$ (C_{bu}/C_{pu}) to evaluate the extent of brain penetration for drug candidates. Total brain/plasma ratio (i.e., B/P) is mostly due to nonspecific binding and does not reflect the potential of compounds to cross the BBB.
- $K_{p,uu}$ is usually preserved across species for nontransporter substrates, which enable prediction of human free brain drug concentration using unbound human plasma concentration.
- For compounds that exhibit distribution equilibrium in preclinical animals and have good passive permeability and no transporter efflux *in vitro*, free drug concentration in the plasma is a good surrogate for free drug concentration in the brain for humans. CSF measurement does not add extra values for the “well-behaved” (group I) compounds.
- CSF is a valuable surrogate for free drug concentration in the brain. However, for efflux transporter substrates, CSF tends to overestimate free drug concentration in the brain.
- Fraction unbound in brain tissue is useful to calculate free drug concentration in the brain. However, it will not affect the unbound brain concentration for orally administered drugs. Fraction unbound should not be optimized through structural modification or be used to rank order compounds.
- P-gp and BCRP are two major efflux transporters in the BBB and they work synergistically to eliminate compounds from the brain. Substrates of efflux transporters demonstrate significant brain impairment. Rodent-based neuroPK studies tend to overestimate efflux activity of human BBB, and monkey is a better preclinical model to predict CNS penetration for human.

- Drug–drug interaction due to inhibition of P-gp or BCRP at the BBB is unlikely at clinical relevant doses, owing to the relatively low free drug concentration compared with K_i for most inhibitors.

17.6 FUTURE PROSPECTS

Our understanding of the BBB has advanced significantly over the years. Strategies and methodologies continue to evolve to help us discover new medicines to treat CNS diseases. We expect to see more imaging techniques applied to early drug discovery programs to guide in-depth understanding of drug–target interactions and mechanisms of actions. The BBB transporter field will continue to expand and the resulting data will be incorporated into building PK/PD models and developing predictive tools. Uptake transporters and carriers will be utilized effectively to enhance influx of drugs into brain. Novel brain delivery technologies will advance to bring impermeable compounds into the brain, such as innovations targeting transporters [87] and nanoparticles [88]. Biologics will be delivered to the brain and be available to treat brain diseases. An example of the current approaches is to use molecular Trojan horses to deliver biologics to the brain [89,90]. More BBB PBPK models will be developed and widely applied to accurately predict brain PK.

18.1 SUMMARY

The use of preclinical *in vivo* models is integral to drug metabolism science. They are used to predict human pharmacokinetics in terms of oral absorption and distribution, including CNS penetration and drug clearance. In addition, *in vivo* models are essential in ensuring compound safety through qualification of human circulating metabolites in toxicology species.

The challenge in the use of *in vivo* models to predict human pharmacokinetics comes in the significant species differences in physiology and active processes (metabolism and transport) between animals and humans. Rat appears to be an appropriate model for the prediction of human oral absorption. For simple passive processes, such as volume of distribution and passive renal secretion, simple allometric scaling shows reasonable predictivity between animals and humans. For an indication of CNS penetration, the rat model has the greatest potential, although species differences in CNS penetration are known. However, when active processes, such as metabolism, biliary excretion, and renal secretion, are considered, species differences in rate and extent can significantly complicate extrapolation to human. These differences also preclude the use of preclinical models for the examination of human drug–drug and drug–food interactions.

As drug metabolism science progresses, much greater use of scalable human *in vitro* assays and *in silico* prediction should replace the use of animals in drug metabolism

studies. Until that time, the use of *in vivo* animal models will remain essential in the drug metabolism field, although great care in their use should be exercised.

18.2 INTRODUCTION

A major aim of drug metabolism science is the description of the journey of a drug molecule through the body. It is important to understand how a molecule moves from its site of administration to the site of action, how long it remains there, and how it is eliminated from the body. These are termed the *absorption, distribution, metabolism, and elimination* (ADME) properties of a drug. It is the story of how the body deals with a drug molecule.

Since the inception of drug metabolism science as a separate discipline during the 1950s, scientists have developed a sophisticated understanding of how a drug molecule is handled by the body and, in many cases, can modulate the physicochemistry of a series of molecules to produce more desirable ADME properties (such as a longer elimination phase half-life) [1–4]. An understanding of the proteins that modulate the metabolism and pharmacokinetics of a molecule has been developed [5–8]. In addition, *in vitro* methods have been introduced, which further the understanding of drug metabolism and allow assessment of large numbers of compounds without recourse to *in vivo* preclinical models.

However, the use of *in vivo* animal models to understand drug disposition remains a key part of the drug discovery and development process. Wherever possible, a drug metabolism scientist has an ethical duty to replace *in vivo* experiments in preclinical species with *in vitro* and *in silico* approaches. However, with the current state of the science, a truly *in vitro* only approach to describe the properties of a molecule is not available. Thus, animals have to be used. The ultimate goal should be to replace all animal experiments with *in vitro* ones. However, until that time, the drug metabolism scientist is strongly recommended to follow a paradigm illustrated in Fig. 18.1, whereby

Figure 18.1 Proposed ADME screening funnel that drives to reduction in animal use.

large numbers of potential drug molecules are triaged using *in silico* and *in vitro* methods with only few compounds progressing to *in vivo* experiments.

From a pharmaceutical industry perspective, most drugs are aimed at the treatment of human disease. Thus, understanding ADME properties in humans is a key part of bringing a drug to the pharmaceutical market. A typical drug discovery and development programme (if successful) will take more than a decade to complete. Typically, medicinal chemists will synthesize thousands of molecules as putative drugs and the research process will reduce these to one or two for detailed scrutiny. During the development phase, the human safety and efficacy of these molecules are fully evaluated for presentation to regulatory authorities (such as the FDA). Drug metabolism science plays a significant role in the entire research and development process, with an interesting change in emphasis during the process. In early research, the aim is to identify pharmacologically active molecules with appropriate human ADME properties, without recourse to human *in vivo* experiments. Once the single compound has been selected, the drug metabolism effort tends to become descriptive with emphasis on a detailed understanding of the ADME profile of that molecule. In both phases, the use of *in vivo* models of drug metabolism is essential. However, there are significant species differences in the way drug molecules are handled from an ADME perspective. These species differences need to be well understood to enable correct decisions to be made.

The animal species used for drug metabolism *in vivo* experiments tend to depend on the phase of the project and the questions posed. In the research phase, the vast majority of animals used are rodents. *In vivo* pharmacology models tend to be in mice and rats and a significant proportion of drug metabolism effort can be expended in support of these models to understand PKPD relationships. As stated previously, the major aim of a research project is to select compounds with desirable ADME properties. Again, the *in vivo* model of choice is the rat, due to its relative availability and low cost. However, other nonrodent species (such as dog and nonhuman primate) are used during this phase. Whatever species is used, it is vitally important to understand the extrapolation of any pharmacokinetic property from the animal species to human. In the development phase, there is a regulatory requirement to complete toxicology studies in one rodent and one nonrodent species. Again the species most often employed are rat and dog or nonhuman primate. However, carcinogenicity studies are completed in mice and reproductive toxicity studies in rabbit. During the development phase, drug metabolism experiments are designed to support toxicology, ensuring that any chemical species derived from the drug in humans (i.e., metabolites) are also exposed to animals during toxicity studies (i.e., there are no human-specific metabolites). Thus, understanding of the metabolite profile of a molecule in mouse, rat, dog, rabbit, and nonhuman primate is important.

18.3 ORAL ABSORPTION

18.3.1 Oral Absorption and Bioavailability in Human

Most human drugs are administered at sites remote from the site at which they are designed to act. For patient ease of administration, the oral route is preferred. Orally administered drugs are most often given in tablet or capsule formulations. In order to be absorbed into the body, these solid formulations must disintegrate in the stomach and release their cargo of drug into aqueous solution in the gastrointestinal (GI) tract fluid.

The human GI tract is designed to be the organ of food digestion and nutrient absorption. The first organ encountered following oral administration is the stomach. This is where food digestion begins and can be a very acidic environment (pH 1–5) depending on the fed status of the individual. The major human drug absorbing site is the small intestine. This part of the GI tract is made up of three separate segments: the duodenum, jejunum, and ileum. In the small intestine, the pH returns to near physiological (pH 6.5–7.4). These segments contain a number of adaptations designed to facilitate the absorption of nutrients (and drug molecules), including luminal folding, villi, and microvilli, which increase the surface area for absorption. Finally, the lower part of the human GI tract is the large intestine (or colon), where the majority of the water involved in food digestion is reabsorbed before defecation.

Once a drug is in solution, it must pass across the GI tract wall to be absorbed into the body. There are two major routes of passage for drug molecules to pass across the GI tract wall: paracellular and transcellular (Fig. 18.2).

The major cellular barrier between the GI tract lumen and the blood is the gut wall epithelial cell or the enterocyte. To be absorbed, the drug must cross the enterocyte barrier. Between each enterocyte, there are very small tight junctions with aqueous pores through which low molecular weight compounds can be absorbed [9]. The estimated sizes of these aqueous pores in human small intestine vary from 5 to 13 Å, and there may be several size populations [10,11]. Drugs of small molecular weight can pass through these aqueous pores and are considered to be paracellularly absorbed. An example of such a drug is cimetidine [12], which is ~60% absorbed in human due to its molecular weight of 252 despite its hydrophilicity (cLog $D_{(7.4)}$ of -0.05). Owing

Figure 18.2 Schematic of the oral absorption process indicating paracellular and transcellular absorption.

to the size constraints and the relatively low surface area covered by these pores, the paracellular route is only a minor route of absorption for drug molecules. In addition, the aqueous pores become smaller lower down the GI tract and as such paracellular absorption from the colon is unlikely.

The major route of drug absorption is the transcellular route. To be absorbed by this route, the drug must dissolve in the apical membrane of the enterocyte and cross the cell to the basolateral membrane, cross that to enter into the blood. Drugs absorbed by the transcellular route are also subject to a battery of drug transporters that can either facilitate the absorption of the compound or act as a barrier to absorption by effluxing the compound back into the gut lumen. In addition, the gut wall cell contains many drug-metabolizing enzymes that can irreversibly remove the drug on passage through the cell.

Once a compound has passed through the gut wall, either by the paracellular or transcellular routes, it is considered to be absorbed into the body. However, it has one further barrier to overcome before it appears in the systemic circulation. All the blood from the gut passes into the hepatic portal vein, which flows directly to the liver. The liver is the major site of drug clearance and as such can exert a profound effect on the systemic concentrations of a drug in a process called *hepatic extraction*. The extent of hepatic extraction will depend on the physicochemistry of the drug and the affinity for drug transporters and metabolic enzymes. Owing to first-pass hepatic extraction, it is entirely possible that a compound can be completely absorbed from the GI tract but show no systemic concentrations due to complete removal by the liver. The extent to which a compound overcomes all the barriers between oral administration and the systemic circulation is called the *oral bioavailability*. It is a composite of the fraction absorbed from the GI tract and the fraction removed on first passage through the liver.

18.3.2 Animal Studies to Calculate Oral Absorption and Bioavailability

In the research phase, much emphasis is placed on the assessment of oral absorption in animal species as a predictor of human oral absorption. The most simple method to estimate oral absorption is by completion of an intravenous versus oral cross-over experiment in the species of choice. Following intravenous administration, all the dose is placed in the systemic circulation. Thus, the area under the plasma/blood concentration versus time curve (AUC) represents the complete dose. For an oral dose, the drug must dissolve in the GI tract contents and cross the GI tract wall (absorption). All the blood from the gut flows into the hepatic portal vein, which flows directly to the liver. The liver is a major drug extracting organ and, in order to reach the systemic circulation, the drug needs to avoid this potential “first-pass” extraction. Consequently, the AUC following an oral dose represents the amount of drug absorbed and the amount escaping first-pass extraction.

If it is assumed that clearance of a drug is solely by the liver, then the first-pass extraction of that drug can be estimated from the clearance of that drug and the hepatic blood flow in that species. Once the hepatic first-pass extraction is estimated, the AUC assuming complete oral absorption can be calculated. The ratio of the observed AUC to that expected following complete oral absorption represents the fraction of the dose absorbed in that species.

A more direct estimate of the fraction of an oral dose absorbed can be determined using the hepatic portal vein experiment. In general, this tends to be completed in

rodent species as it requires sampling of blood from the hepatic portal vein, thus eliminating the need to estimate hepatic first-pass extraction. Basically, the amount of dose absorbed can be estimated using one of two potential equations:

$$\text{Dose absorbed} = Q \times (\text{AUC}_{\text{portal}} - \text{AUC}_{\text{systemic}})$$

$$\text{Dose absorbed} = \text{Cl} \times \text{AUC}_{\text{portal}}$$

where Q is the hepatic portal vein blood flow and Cl the clearance of the drug.

18.3.3 Animal Studies as Models of Human Oral Absorption

The projection of extensive oral bioavailability in humans is often a key goal in pre-clinical drug discovery projects. Consequently, selecting compounds with appropriate oral absorption potential is important. There are significant differences in physiology between the human GI tract and those of animals used in *in vivo* drug metabolism experiments, which need to be understood for successful decision making. The use of animals for predicting human oral absorption has recently been reviewed [13].

18.3.3.1 Rat. The rat is the most studied preclinical model of human oral absorption. There are a number of physiological differences between the GI tracts of human and rat [14,15]. The pH in the rat duodenum tends to be slightly higher than that in human [15]. Clearly, the length and diameter of the human small intestine are higher than that in rat and there is significantly less unstirred water layer (the fluid nearest the gut wall epithelium) in humans than rats [14]. In addition, there are significant differences in terms of the bile system. Bile production in rat is some 16-fold higher than in human [16,17]. In addition, rat bile constantly flows into the GI tract, where it may have a solubilizing effect on low solubility agents. In contrast, all bile production in humans is stored in the gallbladder to be released following feeding. All these characteristics may lead to issues in terms of extrapolation of oral absorption between rat and human. However, in terms of aqueous pores, rat and human are similar with respect to size and distribution, which may suggest that the rat would be an appropriate model for paracellular absorption in humans [18,19].

Rat and human express similar amounts of drug transport proteins at the gut wall. Cao *et al.* [20] showed that several transport proteins (such as PepT1, MRP2, and GLUT5) are similarly expressed in rat and human intestine, whereas others (such as MDR1 and MRP3) are present in both species but at different expression levels. Indeed, the correlation between duodenal expression level of a large number of transport proteins in human and rat exhibited a strong r^2 value of 0.5687. There was a weak correlation between the rat and human expression level of intestinal drug-metabolizing enzymes.

Overall, Chiou and Barve [21] found a strong correlation between oral absorption in rats and humans for 64 drugs, which suggests that the rat is an appropriate model for human oral absorption, in the majority of cases.

18.3.3.2 Dog. A similar analysis of the dog suggests that it is not an appropriate model for human oral absorption under certain circumstances and should be used with caution in the research phase. The correlation between oral absorption in dog and human for 43 drugs was weak [22]. There are a number of potential physiological reasons for this.

In common with the rat, the intestinal pH is higher in the dog than in human. There is a higher bile salt secretion rate and a higher bile salt concentration that may drive to improved oral absorption of poorly soluble compounds [23,24]. In addition, the villus length in the dog small intestine is longer than that in human. Finally, total GI transit time is more rapid in dog than human. All these factors may play a role in the poor correlation between dog and human oral absorption. However, the major driver of this difference may well be the paracellular pathway.

The aqueous pore pathway in the dog assumes greater significance due to larger aqueous pores than human [19]. Many low molecular weight and polar compounds are absorbed by the paracellular route. In humans (and rats), there is a significant molecular weight cutoff with compounds >300 molecular weight exhibiting poor oral absorption by this pathway. However, in dogs, the molecular weight cutoff is higher, leading to significantly greater oral absorption for some compounds in the dog. For example, acyclovir (MW 225) shows <30% absorption in rat and human, whereas in dog, absorption is estimated at 85%. Similarly, atenolol (MW 266) is completely absorbed in dogs, but 22% and 55% absorbed in rat and human, respectively.

Unlike the rat, there appears to be limited information on expression of drug transporter proteins and metabolizing enzymes in the gut wall of the dog. However, species differences in oral absorption do not seem to be limited to paracellularly absorbed compounds in the dog. This is exemplified by the NK₂ antagonist UK-224,671 [25]. This compound would appear to be transcellularly absorbed as a molecular weight of 544 is unlikely to be absorbed through the aqueous pore pathway. It is a P-glycoprotein (P-gp) substrate [26], and this limits its transcellular absorption potential in mouse, rat, and human. However, in dog, the oral bioavailability is 55%, suggesting much greater absorption in this species.

18.3.3.3 Monkey. The use of monkey to predict human oral absorption has not been extensively studied. However, genetic and physiological similarities suggest that monkey may well be an acceptable model. The gastric pH is most like human than any other preclinical species. Gastric emptying time is similar to that in humans, whereas small intestinal transit time is similar to dog [27]. There is a paucity of data on expression levels of drug transporters and metabolizing enzymes in monkey gut.

Chiou and Buehler [28] have shown a good correlation between monkey and human oral absorption for 43 drugs, despite a range of solid dosage formulations being employed. Examination of solid formulations (tablets or capsules) is perhaps where the use of the monkey is most appropriate, since such formulations cannot be given to rats and the dog appears not to be a good model for human absorption. However, the balance of cost and ethics of monkey use needs to be strongly considered and use of this species should be strictly limited to fewer compounds at later stages of drug research.

18.3.4 Modeling the Effect of Food in Animals

A major consideration for human oral absorption is the effect of food on the absorption profile of a drug. The effect of food on the oral absorption of drugs in humans has been extensively reviewed for both general therapeutics [29,30] and for anticancer agents [31].

Food can have profound effects on both the rate and extent of drug absorption for certain compounds. For example, coadministration with food reduces the oral exposure of drugs such as doxazosin, verapamil, and zidovudine. In contrast, the absorption of felodipine, itraconazole, and phenytoin is increased by food. In addition, the rate of absorption is decreased by food for drugs such as diclofenac and paracetamol. Finally, there are significant numbers of drugs (including diazepam and amlodipine), where food has no effect on oral exposure in humans [30].

There are a number of potential reasons for these food effects on oral exposure. Food increases bile acid secretion and gastric retention, which will have an enhancing effect on poorly aqueous soluble agents and a potentially delayed effect on absorption rate. It may also increase hepatic blood flow such that high hepatic extraction drugs show reduced exposure after oral administration.

Given the potential variety of outcomes with food and the significant differences in GI physiology, modeling of human food effects in animals needs to be completed with great care. The rat should be ruled out as a model to predict food effects in humans due to its continuously high bile flow. It is also very difficult to achieve a truly fasted rat as on withdrawal of food, rats will tend to eat bedding or fecal pellets, meaning that there is always material in their stomachs. Dogs are not an appropriate model of human oral absorption in general as shown above. However, there are some accounts of the use of the dog in this context in the literature. For example, it has been shown that the food-driven 33–46% decrease in oral AUC of hydralazine in humans is adequately predicted by a food reduction in AUC of 63% in the dog [32]. However, celecoxib shows hardly any change with feeding in humans but a three- to fivefold increase in systemic AUC in the dog [33]. Finally, due to genetic and physiological similarities, the monkey may be an appropriate model, but there are very few examples of its use for studying food effects in the literature. It would appear that with state-of-the-art physiologically based pharmacokinetic models available (reviewed elsewhere in this book), the *in silico* approach to measure food effects in humans has largely superseded the preclinical study.

18.3.5 Oral Absorption Summary

Great strides have been made in the recent past in predicting human oral absorption in the research phase. Compounds with appropriate physicochemistry for oral absorption and acceptable *in vitro* absorption profiles will continue to be taken forward to pre-clinical animal species for oral absorption and bioavailability determination. The most appropriate species for this investigation is the rat based on its correlation with human oral absorption. The dog is not an appropriate model of human oral absorption and should be used with great care and a mechanistic understanding of the absorption process. Monkey may be an appropriate model but should only be used on rare occasions when solid dosage forms need to be investigated.

18.4 DISTRIBUTION

Distribution describes the reversible movement of a compound from the systemic circulation into tissues. It is dependent on the physicochemistry of the molecule driving a balance between plasma protein binding and tissue affinity [34].

18.4.1 Extrapolation of Animal Distribution to Human

The prediction of human volume of distribution has been extensively reviewed by Obach [34].

Since tissue distribution is driven by plasma protein binding and tissue affinity, extrapolation of the human volume of distribution from animal studies tends to be relatively straightforward. In general, tissue distribution is a passive process and tissues tend to show no real species differences (made of cells and membranes).

Therefore, it is possible to predict the human Vd of a particular drug using allometric (body weight) scaling [35]. The allometric exponent tends to approximate to unity [36,37]. However, in the early phase of drug research, the requirement for pharmacokinetics in three species to perform true allometric scaling can be limiting. Thus, many groups have tended to search for a single species that is as predictive for human Vd.

Obach *et al.* [38] examined several methods of prediction of human Vd. They found that allometric scaling of Vd (based on total drug) gave a relatively poor prediction of human Vd (53% of compounds with ± 2 -fold of actual human Vd). This improved significantly (77% within ± 2 -fold) if the unbound parameters were used. In addition, direct scaling of dog Vd corrected for species differences fraction unbound performed as well (81% within ± 2 -fold).

Other groups have examined alternative species for single species extrapolation of human Vd. Ward and Smith [39,40] used a correlation analysis to show that the monkey is an appropriate predictor of human Vd, whereas rat and dog showed less predictivity, based on total drug parameters. The same group recognized that the monkey may not be the most appropriate species to use in early drug research and have proposed incorporation of physicochemical rules to determine the likelihood of extrapolation errors from preclinical species [41]. Finally, Caldwell *et al.* [42] have shown that the extrapolation of rat Vd can exhibit a reasonable approximation of human Vd (average fold error 1.85 for 144 compounds with 84% of compounds with ± 3 -fold of actual human Vd), although this analysis does not factor in any species differences in fraction unbound between rat and human.

In summary, extrapolation of preclinical species Vd values is likely to provide a reasonable approximation of human Vd, especially when species differences in plasma protein binding are taken into account.

18.4.2 Free Drug Hypothesis

As described above, drug distribution is generally a passive process where there are no major barriers to drug diffusion into tissues. In these cases, eventually a steady-state situation arises, whereby the unbound concentration in blood reflects the unbound concentration in the tissues. Thus, for a large number of drugs, the unbound concentration in blood is a surrogate for the unbound concentration at the target. This is termed the *free drug hypothesis*.

18.4.3 Barriers to Passive Drug Movement

Within the body, there are a number of significant barriers to the passive movement of compounds between the blood and the tissue of interest. These include the

blood–eye and the blood–testis barrier. However, by far, the most important barrier is the blood–brain barrier (BBB).

The BBB acts as a highly selective barrier to the passage of compounds into the CNS. It is formed by the endothelial cells of the blood vessels supplying the brain. Unlike blood vessels supplying many other tissues, these cells form extremely strong tight junctions that effectively mean that the aqueous pore pathway does not exist. In addition, the membrane phospholipid make-up may be different from other endothelial cell membranes with a more rigid structure leading to increased difficulty in passive permeation. Finally, the cells express significant levels of efflux transporters and metabolic enzymes that are capable of removing compounds back into the blood on passage across the BBB.

By far, the most studied efflux transporter at the BBB is P-gp. Chen *et al.* [43] have extensively reviewed P-gp and P-gp knockout mice. The role of P-gp in preventing BBB penetration has also been extensively reviewed. The presence of P-gp as an efflux protein makes the BBB a formidable barrier for the passage of drug molecules. Molecules that are slow to permeate the endothelial cell membrane can be effectively removed and placed back into the blood by P-gp (and other efflux transporters). This has been exploited in the H1 antagonist area to provide drugs that show limited CNS penetration and thus the potential to exert a peripheral effect without the sedation side effects associated with central H1 antagonism. For example, fexofenadine is a potent H1 antagonist that is used in the treatment of allergic rhinitis. It is believed to be a substrate for P-gp and other drug transporters [44], and it is this aspect that prevents its entry into the brain and drives its lack of sedation activity versus earlier H1 antagonists [45,46].

In contrast, many drugs need to enter the CNS to exert their effects and so understanding brain penetration is a key feature for many drug research projects. This understanding often relies heavily on preclinical animal models.

18.4.4 Evaluation of CNS Penetration Preclinical Species

The evaluation of the potential of a compound to enter the CNS begins with the understanding of physicochemistry and the use of *in vitro* models of cell permeability. Promising compounds arising from these models are likely to be progressed to rodent studies. The major issues facing such studies are the route of administration and evaluation of which matrix to measure. Rodents are used because the end point is often cerebrospinal fluid (CSF) or brain tissue.

It is important to measure brain penetration, while plasma concentrations are as stable as possible. Following intravenous bolus administration, often the plasma concentrations decline rapidly during the early time points. Thus, brain concentrations may lag behind plasma concentrations at early time points, leading to an underestimate of CNS penetration (Fig. 18.3a). Following oral administration, the concentrations tend to rapidly rise and then fall as the compound is cleared. By far, the most appropriate route is the intravenous infusion to steady state (Fig. 18.3b), where the compound is infused at a constant rate for several hours, such that there is a steady rise in the plasma and potentially brain concentrations to a plateau, where the rate at which the compound is dosed is equivalent to the rate at which it is cleared.

The most simple measurement made in CNS penetration studies is the total concentration in the brain relative to the total concentration in the plasma (the brain to

Figure 18.3 (a) Schematic of plasma and brain concentrations following an intravenous bolus administration assuming relatively slow CNS penetration. (b) Schematic of plasma and brain concentrations following intravenous infusion to steady state.

plasma ratio). Thus, at the end of the experiment, the animal is sacrificed and the brain removed. It is then homogenized and the brain homogenate analyzed for drug concentrations. This experiment assumes that binding to the brain tissue is the same as the binding to plasma proteins, and consequently, the free concentrations are equivalent. However, there are several issues with this approach. First, brain tissue is highly lipophilic and binding of lipophilic molecules is likely to be higher than that in the plasma. Thus, a compound with a brain to plasma ratio of greater than one, may reflect higher binding to brain tissue with the potential that unbound concentrations are low. Thus, a high brain to plasma ratio does not necessarily mean that the compound will have a therapeutic effect. Conversely, many lipophilic acid molecules bind tightly to plasma proteins with potentially less binding to brain tissue. Thus, total measurements may well underestimate the CNS penetration of such molecules.

The other potential issue with this experiment is that it is not possible to completely remove the blood from the brain before sacrifice. Since blood represents a small proportion of the volume of the brain tissue, compounds with high blood concentration may appear to have significant brain penetration.

Other groups have determined the extent of binding of a compound to brain homogenate and used this to calculate an unbound concentration in the tissue. This can be related to unbound concentrations in the plasma and is a more relevant measure of brain penetration and potential to achieve therapeutic concentrations in the CNS [47]. Thus, it is important to consider unbound concentrations in the CNS to fully define CNS penetration. The unbound concentration to measure would be the extracellular fluid (ECF), but this is a very difficult matrix to sample. Many groups have attempted to use microdialysis to sample ECF, but in the main, these have been hampered by the need for considerable surgical skill and the time-consuming experiments needed to quantify recovery of the probes. Another surrogate of the ECF is the CSF. This is a largely protein-free fluid that fills the ventricle in the brain. It is relatively easy to sample in the rat and can be compared to the unbound concentration present in the blood. The downside of this measurement is that the CSF concentrations may not necessarily reflect the ECF concentration, since there is a barrier between the CSF and the brain, which also expresses efflux transporters.

The other major issue with CNS penetration experiments in rodents as a model of human CNS penetration is that it is difficult to obtain good estimates of the human CNS penetration of a compound. Clearly, it is not possible to sample brain or complete microdialysis in humans, and the collection of CSF is challenging. The most appropriate method to achieve a measurement of CNS penetration in humans is to complete a PET imaging study, which requires significant investment and has not been completed on large numbers of compounds. Therefore, overall, it is very difficult to compile good data sets of CNS penetration in human for comparison with rodent experiments.

As a “rule of thumb,” if a compound readily penetrates the CNS in a rodent, it is likely that it will readily penetrate the human CNS, making rodent studies the *in vivo* model of choice for CNS penetration. However, the issue with the use of the rodent is that there may be species differences in the efflux transporters at the BBB. In a recent study, species differences in the brain penetration of three P-gp substrates were examined by PET methodology [48]. This group found that verapamil, GR-205171, and altanserin penetrated the CNS of humans and monkeys more readily than rat brain. In addition, this species difference remained when P-gp was inhibited by administration of cyclosporin, suggesting that other efflux transporters or a unknown active process may be responsible for this difference.

18.4.5 Summary of Preclinical Models of Drug Distribution

The potential for a drug to distribute into tissues is an important consideration in the study of drug disposition. Distribution is a largely passive process determined by the physicochemistry of the drug. Tissues are largely made up of cells with membranes and so lipophilic molecules are more likely to distribute into tissues.

There are no major species differences in the composition of tissues. Therefore, preclinical species are appropriate models of drug distribution in humans. The most appropriate extrapolation to human involves the allometric (body weight) scaling of

the unbound parameter (i.e., corrected for any species differences in plasma protein binding) using an allometric exponent of 1.

The free drug hypothesis suggests that under equilibrium conditions, the unbound concentrations in the plasma reflect those in the tissues. Thus, if a research project is using an animal model of pharmacology, then the measured unbound concentration in plasma giving the desired effect should be close to the target efficacious concentration in humans (assuming no pharmacological potency differences).

The free drug hypothesis may not hold when the pharmacological target is behind a barrier to passive drug movement (such as the BBB). In this case, the ability of the drug to cross the barrier and the unbound concentrations in the tissue are of prime importance. In the absence of strongly validated preclinical models of human CNS penetration, rodent CNS penetration is likely to reflect that in human, so long as unbound concentrations are considered.

18.5 EXCRETION AND ELIMINATION

The human body is constantly renewing itself by turnover of proteins and other macromolecules. Similar turnover processes apply to drug molecules. Any administered drug is subject to removal from the body by a variety of processes. The removal of drug-related material (compound and metabolites) from the body is called *elimination*. The excretion of drug-related material is similar but usually refers to the organ that removes the drug (usually the liver and the kidney).

Drugs are removed from the body at different rates, depending on the rate at which they are acted on by excretion and elimination processes. The quantitation of the rate of removal of a drug from the body is an important consideration and is captured by the pharmacokinetic concept of clearance.

18.5.1 Allometric Scaling of Clearance

It follows that human clearance is an important parameter to be able to predict from preclinical information. This is because it in large part determines the exposure of a compound for a given dose.

The most widely used method of prediction of human clearance from preclinical pharmacokinetic information is allometric scaling. This attempts to relate the clearance of a molecule to the body weight of the species investigated. The basis of this scaling dates back to an early paper [49], which suggested that metabolic rates could be related to body size using an allometric exponent of ~ 0.75 . Boxenbaum [50] developed this further by showing that physiological parameters such as liver weight and hepatic blood flow can be correlated to body weight with allometric exponents of 0.8–0.9.

The rationale behind simple allometric scaling is that clearance can be related to body weight using the following equation:

$$\text{Clearance} = a \times \text{body weight}^x$$

where a is a constant and x is the allometric exponent.

Thus, a plot of log clearance (mL/min) versus log body weight (kg) would be a straight line with a slope being the allometric exponent (Fig. 18.4).

Figure 18.4 Principle of simple allometric scaling.

Using this method, the clearance of a compound in human could be predicted from extrapolation of the line to human body weight.

The success rate of simple allometric scaling in prediction of the human clearance of 102 molecules has been evaluated by Tang and Mayersohn [51]. The allometric exponents ranged from 0.26 to 1.2, although the majority were in the range 0.6–0.8. Overall, the average prediction error (APE) for this compound set was 254%. However, the authors noted that the application of simple allometry could be prone to some highly significant individual errors, in some cases over 1000%. Furthermore, they noted that the majority of these large errors seemed to occur in the low clearance (with respect to hepatic blood flow) cohort. Indeed, the low clearance cohort showed an APE of 598%, whereas the high clearance cohort showed an APE of only 47%. Their analysis suggested that a compound was more likely to be mispredicted to a large extent when the *cLog P* was >2 and the species difference in plasma fraction unbound was >5 . They rationalized this finding on the basis that for high clearance agents, the major contributor to that clearance by the liver or kidney was the hepatic or renal blood flow. Since blood flows scale well allometrically, so will high clearance agents. In contrast, the major determinant of low clearance is the unbound intrinsic clearance of the molecule for the clearing process (likely to be metabolism or active transport). For these clearance pathways, as will be shown later, significant species differences exist that will introduce error to the allometric extrapolation. This would fit with the overall suggestion that passive processes are likely to scale well allometrically, whereas active processes are prone to species differences and therefore error in extrapolation.

In addition to the potential for significant prediction errors, there are a number of issues with simple allometry for the prediction of human clearance. First, it requires pharmacokinetic studies in at least three species and so it is not especially amenable to compound selection in early drug research. Second, it is nonmechanistic and does not take into account the clearance mechanism of a particular molecule nor the potential for species differences in the rate of active processes. Finally, although the initial idea was that clearance would scale with an exponent similar to that with which physiological processes scale, the exponents for simple allometric scaling of clearance can show

significant deviation from 0.7 to 0.8. Indeed, Mahmood and Balian [52] argue that there is no reason why the allometric exponent for a particular drug should be 0.7–0.8. These authors have shown that human clearance prediction is improved by the incorporation of factors depending on the allometric exponent. When the allometric exponent is between 0.55 and 0.70, simple allometry predicts most accurately. For exponents of between 0.71 and 0.99, the maximum lifespan potential should be incorporated, and for exponents above 1, clearance multiplied by brain weight is more accurate. For a more in-depth analysis of the use of allometry with the rule of exponents, the reader is directed to several papers by Mahmood [37,53].

To address the requirement for pharmacokinetic studies in multiple species, several groups have proposed methods of human clearance prediction using scaling from one single species. One of the most comprehensive evaluations has examined the hepatic blood flow method [39–41], whereby the human clearance is predicted from the product of the animal clearance and the ratio of the human and animal hepatic blood flow. For a series of 103 compounds, the monkey hepatic blood flow predicted human clearance more successfully than rat or dog or the use of simple allometric scaling. Although these authors concluded that use of the monkey method was quantitatively more predictive than other species, they recognized that use of the monkey in early drug research projects is problematic. For this reason, other authors have proposed the use of single species allometric scaling from rat using a fixed exponent of 0.75 as a pragmatic and reasonably predictive method for the prediction of human clearance [42,54].

The use of fewer species and the incorporation of fixed exponents single species scaling is highly controversial [55,56]. This author argues that allometric exponents have no physiological relevance. The use of a fixed exponent of 0.75 is misleading and prone to significant prediction error. As shown previously, the preferred method is multiple species allometry using the rule of exponents.

Irrespective of the literature controversy, it appears that the use of preclinical species to predict human clearance will continue. This is despite the fact that no universal method appears to have the required degree of accuracy to predict differences between two closely related compounds [57]. In addition, many of these methods can produce some highly misleading human clearance predictions (probably as a result of species differences in active clearance processes).

18.5.2 Clearance Processes

There are a number of ways a drug can be eliminated from the body. The major routes are by metabolism, via the bile and via the urine. In a survey of the top 200 marketed drugs [58], by far, the predominant route of elimination was by metabolism. The second major route was in the urine, with only small numbers of compounds being eliminated in the bile.

18.5.2.1 Metabolism of Drugs. In the same review [58], the enzymes responsible for the metabolism of the top 200 marketed drugs were investigated. By far, the most predominant enzyme responsible for metabolism is the cytochrome P450 (CYP) family. The next most prominent drug-metabolizing enzymes are the UDPGlucuronyl transferases (UGTs), followed by more minor contributions from aldehyde oxidase (AO), monoamine oxidase, and sulfotransferases.

18.5.2.2 Cytochrome P450 (CYP) Metabolism. The CYPs are a superfamily of drug-metabolizing enzymes that, in general, catalyze the oxidation of drug substrates. In the main, they cause the hydroxylation of carbon atoms and the dealkylation at heteroatoms such as nitrogen or oxygen. They are expressed in many tissues, but the greatest expression occurs in the liver.

The CYPs comprise a family of several hundred isoforms, but by far, the most important human drug-metabolizing CYPs are CYP3A4, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP1A2. Each has its own structure substrate metabolism relationship.

18.5.2.3 Preclinical Models of CYP Metabolism. There are a number of distinct species differences in the structure and function of the CYPs. The same isoforms are not expressed across the preclinical species [59].

Table 18.1 shows the significant differences in the expression and substrate specificities of CYP isoforms between human and animal species. These marked species

TABLE 18.1 Species Differences in the Expression of CYP Isoforms

CYP Subfamily	Species Extrapolation	Inhibition	Induction
CYP1A	Strong conservation across species	Human inhibitor furafylline shows variable inhibitor profile in preclinical species	Omeprazole induces in human but shows variable induction in animals
CYP2A	Significant species differences in substrate specificity	NA	Different inducers in animals and humans
CYP2B	Different isoforms with different substrate specificities	Similar inhibitor profile across species	Phenobarbital induces in all species
CYP2C	Sex-dependent expression in rats. Poor expression in dogs. Significant substrate specificity differences between animals and humans	Inhibition by sulfaphenazole in human, monkey, and dog. Limited inhibition in rat	Inducible in humans
CYP2D	Polymorphic expression in human	Inhibition by quinidine in human, monkey, and dog but not rodents. Inhibition by quinine in rat, dog, and monkey but not human	Not inducible
CYP2E	Relatively well conserved across the species	Similar inhibitory profiles	Inducible by ethanol and acetone
CYP3A	Markedly different substrate specificities across the species	Species differences in inhibition	Species dependency in induction

differences (depending on the isoforms in question) could lead to major differences in clearance by CYPs across the species. Given that a large proportion of marketed agents are cleared by CYP metabolism, it is perhaps not a surprise that allometric scaling based on body weight shows moderate predictivity, with the potential for large extrapolative errors [51]. For these substrates, human liver microsomal scaling may be a more appropriate clearance prediction method.

In addition, there are striking species differences in the CYP inhibition and induction profiles. For these reasons, CYP induction or drug–drug interaction (DDI) studies in animal species as predictors to human are not recommended.

18.5.2.4 UDPGlucuronyl Transferases. The UGTs are a family of drug-metabolizing enzymes that catalyze the addition of glucuronic acid at phenol, alcohol, acid, and nitrogen functions. There are a significant number of isoforms expressed in human liver, including UGT1A1, UGT1A3, UGT1A6, UGT1A9, UGT2B7, UGT2B10, and UGT2B17. In addition, there is significant expression of UGTs in human intestine that can contribute to reductions in oral bioavailability due to gut wall first-pass glucuronidation.

As for the CYPs, each UGT has its own structure substrate metabolism relationship. Unlike CYPs, there has been limited research into the SAR of UGTs. However, some species differences in glucuronidation are beginning to emerge in the literature. For example, the major human urinary metabolite of afloqualone is an *N*-glucuronide that is not present in the urine of animals. *In vitro* studies suggest that the rate of glucuronidation is significantly higher in human liver microsomes than in microsomes from rat, dog, and monkey liver [60]. In addition, mycophenolic acid was glucuronidated at a higher rate in human liver microsomes than in rat liver microsomes [61]. Finally, there is a significant species difference in the oral bioavailability of raloxifene (39% in rat and 2% in human). It has been suggested that this is driven by a 33- to 72-fold difference in the rate of 4-hydroxy glucuronidation between human and rat intestinal microsomes, leading to a much greater intestinal first-pass extraction in humans.

In common with clearance by CYP enzymes, these potential species differences in glucuronidation will complicate extrapolation of human pharmacokinetics from animals. Thus, for such active metabolism processes, allometric scaling may be seriously flawed.

18.5.2.5 Aldehyde Oxidase. Of the more minor enzymes contributing to metabolism of drugs, AO potentially exhibits the most marked species differences. This enzyme is a cytosolic molybdenum-containing protein that tends to oxidize substrates on heterocyclic nitrogen-containing groups.

There are a number of documented observations of significant species differences in AO expression and activity. These include a potential null polymorphism in Sprague-Dawley rats [62] and the total absence of activity in the dog [63]. In those species where AO is expressed, there appears to be significant differences in activity with monkey showing greater activity than rat [64]. Sahi *et al.* [65] suggest that the rank order of AO conversion of vanillin to vanillic acid is monkey > mouse > human > rat.

These species differences in activity follow through to *in vivo* pharmacokinetics. The clearance of SB-2777011 (an AO substrate) was low to moderate in rat and dog, leading to moderate oral bioavailability [63]. However, in monkey, clearance approximated to hepatic blood flow and oral bioavailability was 2%. *In vitro* investigations

Figure 18.5 Schematic of renal excretion at the nephron.

suggested that human liver cytosol metabolized SB-277011 at an equivalent rate to that of monkey, suggesting the potential for low human oral bioavailability.

Overall, when AO is the principal contributor to the metabolism of a compound, care must be taken in the choice of species for human clearance prediction. The absence in dog and the low and polymorphic expression in rat suggest that these species are not suitable models for human AO clearance.

18.5.2.6 Renal Elimination. A second major human route of elimination is in the urine. Renal elimination of drugs has four distinct contributors (Fig. 18.5):

- Passive filtration of unbound drug at the glomerulus
- Transporter-mediated renal secretion into the urine from the blood
- Extent of passive renal reabsorption from the urine
- Transporter-mediated renal reabsorption from the urine

The amount of a drug excreted unchanged in the urine will depend on the balance of these four activities.

18.5.2.7 Passive Processes. Blood flows into the Bowman's capsule in the kidney where it is subject to filtration. Large components such as blood cells and plasma proteins do not pass through the filter and are retained in the blood. Small molecules (including drugs) that are not bound to plasma proteins are filtered into the proximal convoluted tubules.

For a compound that is not subject to active processes, the amount excreted in the urine will depend on how much of the drug returns back into the blood by passive diffusion across the epithelial cell of the proximal convoluted tubule. This, in turn, depends on the physicochemistry of the drug. Lipophilic drugs are likely to permeate across the membranes and be reabsorbed, leaving very little in the urine. Polar drugs have difficulty permeating membranes and consequently remain to be excreted in the urine. A good example of a passively renally cleared compound is a gabapentin, which shows essentially complete renal excretion at glomerular filtration rate (GFR; clearance 9.5 mL/min/kg) in rat [66] and human (clearance 1.8 mL/min/kg) [67].

Since the latter type of compound tend to be minimally plasma protein bound, their clearance tends to relate to the rate of blood flow to the glomerulus (i.e., GFR). Human GFR is ~ 1.5 mL/min/kg; consequently, the human clearance of gabapentin is

close to 1.5 mL/min/kg. In addition, because this is a passive process, it relates to GFR across the species. Since blood flows are allometrically related, the clearance of such molecules in preclinical species is often an accurate predictor of the human clearance.

A similar relationship holds for compounds that are predominantly passively renally cleared but show a significant degree of passive reabsorption. This is exemplified by fluconazole. Urinary excretion of unchanged fluconazole is the predominant route of elimination across all species. Fluconazole is also highly passively permeable and a constant 80% of the filtered material is reabsorbed from the proximal convoluted tubule. Thus, the renal clearance of fluconazole is ~20% of GFR across the species and scales extremely well allometrically from animals to human [68].

18.5.2.8 Active Processes. Some drugs are substrates for active transporters in the kidney. They can be extracted from the blood and effluxed across the proximal convoluted tubule epithelium by these drug transporters. Such compounds have renal clearances above that which is possible by GFR alone. A good example is lamivudine with 70% of the dose excreted unchanged in the urine in humans with a clearance of 20 mL/min/kg (i.e., greater than GFR [41]).

Conversely, some compounds are substrates for active reabsorption from inside the proximal convoluted tubule back into the blood. Such compounds show predominantly urinary excretion, but their clearance values tend to be significantly less than possible by GFR.

The kidney transporters are beginning to be elucidated and include organic anion transporters (OATs), organic cation transporters (OCTs), and organic anion transport proteins (OATPs) [7,8]. However, the preclinical transporters are not yet fully elucidated and (as with the CYPs) there are likely to be significant species differences in expression and activity. Therefore, allometric scaling of the clearance of such molecules may be problematic, suggesting that preclinical models may not be good predictors of human active renal excretion.

18.5.2.9 Biliary Elimination. Hepatobiliary elimination is a three-step process, most of which is driven by active transport. The first stage is uptake into the hepatocyte usually by drug transport proteins (such as OATPs) at the sinusoidal membrane of the hepatocyte. The compound is transferred across the hepatocyte, avoiding metabolism, to the biliary canalicular membrane. Active efflux into the bile is completed by biliary canalicular transporters, such as MRP2 and BCRP.

There are a number of species differences in the biliary elimination process. First, as with all active transport processes, there are species differences in the drug transporters involved, both in terms of expression and structure activity relationships. For example, it is thought that MRP2 expression at the rat canalicular membrane is significantly greater than that at the human canalicular membrane, whereas dog and monkey expression is similar to human [69]. In addition, the physiology of the rat biliary system is significantly different from human (and other species). Rat bile flow is some 16-fold higher than human [70]. In addition, rats do not have a gallbladder and bile continually flows into the gut lumen. In humans and higher preclinical species, the bile is stored in the gallbladder and is released into the gut lumen on feeding.

For these reasons, the rat tends not to be a good model of human biliary elimination. Some compounds can show high hepatic extraction in rat due to biliary elimination, which does not always translate to similar hepatic extraction in humans. A good

example of this is susalimod [71], where allometric scaling between preclinical species predicted relatively well, but there was a significant overprediction of human clearance (predicted 1.8 mL/min/kg vs actual 0.07 mL/min/kg). Indeed, allometric scaling of clearance by biliary elimination is fraught with difficulty and various scaling factors have been suggested [70].

The other major difficulty with the study of biliary elimination in humans is access to the bile. Sampling of bile in humans requires surgical cannulation of the gallbladder and so examples of true biliary elimination are limited. In addition, compounds with biliary elimination in rat tend to show significant hepatic extraction in this species. Simple allometric scaling of these types of compounds is likely to predict extensive clearance in humans, and so they may be selected out of the compound optimization process. Thus, these aspects may well explain the relatively few examples of biliary eliminated molecules in the top 200 marketed drugs list [58]. As transporter science evolves and understanding of biliary elimination is improved, this situation may change.

18.5.2.10 *In Vivo Models of Human Clearance.* A major driver for completion of *in vivo* pharmacokinetic studies in preclinical species is the prediction of human clearance. The most appropriate experiment is the intravenous administration of the compound followed by extensive blood or plasma sampling. The dose used is important as clearance can be saturable, so the dose needs to be in a similar range to that expected in humans. The plasma or blood clearance can be related to plasma or blood concentrations as shown previously. Comparison of blood clearance with hepatic blood flow will give an indication of the hepatic extraction of the compound (especially if the drug is solely cleared by the liver). The blood clearance (or more appropriately the unbound clearance in blood) can be allometrically scaled (as described previously) to gain a prediction of the human clearance of that molecule.

A further advantage of the preclinical *in vivo* pharmacokinetic study is the ability to collect other matrices and examine the fate of circulating metabolites of the compounds. The measurement of unchanged compound in urine will give an indication of the renal clearance. When compared with the GFR, such experiments yield the potential for a compound to be passively filtered or actively transported to or from the urine.

The determination of biliary elimination of unchanged drug cannot be determined from a simple *in vivo* pharmacokinetic study. The collection and measurement of bile requires surgical cannulation of the bile duct. For this reason, the rat is most often the species of choice. Pharmacokinetic studies can be conducted in bile duct cannulated rats, which has the advantage of relating plasma clearance to the biliary excretion rate. An alternative experiment that can be used to examine biliary elimination is the isolated perfused rat liver (IPRL). This has the advantage of enabling rat hepatic extraction as well as the biliary excretion of unchanged drug and metabolites to be determined. A good example of the use of the IPRL is shown in the examination of the disposition of 5,6-dimethylxanthenone-4-acetic acid, where unchanged drug accounts for 28% of the administered dose with the acyl glucuronide accounting for >50% of the dose [72].

Given the species differences in clearance and the variety of potential mechanisms by which a compound can be removed from the body, the use of preclinical species to model DDIs is fraught with difficulty. The choice of DDI perpetrator for any compound would be difficult, as would be the dose at which it should be administered. These facets are well established for humans and can be modeled using *in silico* techniques. Therefore, the study of DDIs in preclinical models is not recommended.

18.5.3 Metabolism and the MIST Guidance

One of the most important aspects of the use of *in vivo* models of drug metabolism comes in the drug development phase. It is essential that drugs are safe for administration to humans. This is achieved through rigorous toxicology testing in preclinical species. In these studies, it is extremely important that not only the unchanged drug is qualified in humans but also the metabolites of that drug. Thus, it is essential to show that any compound-related material that is exposed to humans has also been exposed to at least one toxicology species with no toxicological consequences. In general, this is achieved by administration of radiolabeled drug to the preclinical species used in toxicity testing. Assuming that the site of radiolabeling has been chosen appropriately, any circulating or excreted drug-related material will also be radiolabeled, and these components need to be identified and quantitated. Indeed, Metabolites in Safety Testing (MIST) guidance from the FDA and subsequent ICH M3 guidelines require any metabolites constituting more than 10% of drug-related material circulating in human plasma is qualified in each toxicology species. Thus, these types of *in vivo* studies represent a major component of the ADME package for a drug submission.

18.5.4 Summary of Preclinical Models of Clearance/Elimination

The clearance of a drug is an important parameter in humans as it relates dose to exposure. There are many ways by which a drug can be removed from the human body. Many drugs are cleared by metabolism with a significant proportion removed by active or passive renal excretion. In addition, biliary elimination of unchanged drug is another potential route. The active processes require intervention from proteins (enzymes and transporters) within the body. There are a number of species differences in terms of expression and structure activity relationships. This makes extrapolation of human clearance from preclinical animal models difficult.

Allometric scaling has been moderately successfully used to predict human clearance. However, it is likely that allometric scaling will work very well for passively cleared compounds and those that are cleared at close to hepatic blood flow (as these are dependent on blood flow and scale well with body weight). The issue comes in the extrapolation of clearance by active processes, where species differences will confound scaling on the basis of body weight and potentially lead to large errors in extrapolation.

At present, extrapolation of human clearance from preclinical *in vivo* models remains an appropriate method for most clearance pathways. The exception is CYP clearance where scaling of human liver microsomal experiments should be more appropriate. As drug metabolism science moves on, further scalable human *in vitro* models of clearance should be advanced that will reduce the need for *in vivo* animal models in this area.

18.6 PERSPECTIVE ON THE USE OF *IN VIVO* MODELS OF DRUG METABOLISM

The use of *in vivo* models has been integral to the progression of drug metabolism science. These models are used extensively to predict the human disposition of potential drug molecules and to support the progression of compounds through drug development, especially in support of toxicology studies. These *in vivo* models are likely to

TABLE 18.2 Summary of the Utility of Animal Models of Drug Metabolism for Predicting Human Drug Disposition

ADME Property	Model Species	Comments
Oral absorption	Rat correlates with human	Rat is an appropriate model for transcellular and paracellular absorption
	Monkey correlates with human	Paracellular pathway in dogs is larger
	Dog has a poor correlation with human	
Effect of food on oral absorption	No appropriate model for human	Rat physiology is different (bile flow). Difficult to fast rats. Dog precluded by physiology differences and paracellular pathway. Use <i>in silico</i> models
Volume of distribution	Scales well from all species, especially if fraction unbound considered	Passive processes scale well from preclinical species
CNS penetration	Rodent models appear best for human prediction. Must use unbound fraction in brain or CSF. Emphasis on which matrix to measure in rodent and human	<i>In vitro</i> systems should be used to triage compounds before <i>in vivo</i> evaluation
Metabolic clearance	Significant species differences. Will scale well for clearances approaching hepatic blood flow. For low clearance agents may be prone to errors due to it being governed by intrinsic clearance	For CYP substrates, human liver microsomal scaling may be a more appropriate predictor of human clearance. As scalable human <i>in vitro</i> systems become available, the use of animal models for human metabolic clearance prediction should reduce
Renal clearance	Passive renal clearance scales well from any preclinical species. Active secretion or reabsorption likely to be prone to species differences	For passive renal clearance, human clearance of unbound drug should approximate to human GFR. Prediction of active process should benefit from identification and expression of the transporters involved
Biliary clearance	Active process. Likely to be species differences. Physiology differences	Prediction of biliary clearance will continue to be problematic until human scalable <i>in vitro</i> assays become available
Drug–drug interactions	Likely to be poor predictivity due to species differences in clearance	DDI studies not recommended in animals. CYP DDIs are well predicted using <i>in silico</i> models

continue to be used into the future, but as drug metabolism science evolves, there needs to be continual scrutiny on their effective use. Every scientist who uses animals in his/her research has an ethical responsibility to minimize that use and replace with suitable *in vitro* alternatives. Drug metabolism has many future opportunities to do this.

A perspective of the current use of *in vivo* models of drug metabolism to predict human disposition is reviewed in Table 18.2.

It is clear that there are many issues with prediction to human and a number of approaches (*in silico*, *in vitro*, and *in vivo*) can be taken. For example, on the whole, for prediction of human oral absorption, it appears that the rat is a good model and indeed the rat can be used successfully for the prediction of volume of distribution and several clearance processes, especially passive processes. When active processes contribute to clearance, species differences complicate extrapolation to human and predictivity is not at the level required. Finally, drug–food and drug–drug interactions are complicated by physiology and species differences and preclinical *in vivo* experiments are not recommended.

As drug metabolism science evolves and the human proteins modulating drug disposition are discovered and evaluated, there will be the opportunity to replace animal use with scalable *in vitro* assays. As this continues, drug metabolism scientists need to continually reassess the appropriate use of *in vivo* models of drug metabolism.

19.1 SUMMARY

There are a variety of genetically modified animal (GEMA) models available to gain insight into the role that drug-metabolizing enzymes (DMEs), nuclear transcriptional factors, and transporters play in the disposition of drugs and in the regulation of endogenous substrates. These systems often work in concert to eliminate compounds from the body and are sometimes associated with drug-induced toxicities.

A GEMA for drug metabolism research is typically a mouse, whose genome has been changed by genetic engineering modifications. There are several approaches commonly used to generate genetically modified mice. The first method involves pronuclear injection of a human gene into a single mouse embryo cell, where the introduced gene will randomly integrate into the mouse genome, creating a transgenic animal. This method creates “knock-in” animals. A second method involves modifying the mouse embryonic stem (ES) cells with a DNA fragment containing an alteration in the mouse target gene, such as the deletion of all or part of the gene, or insertion of foreign genes, such as an antibiotic-resistance gene. The modified stem cells that contain the altered genomic DNA are selected by DNA sequencing and are then injected into mouse blastocysts. This method creates the “knock-out” (KO) animal models. Alternatively, partial replacement of mouse cells with human cells (i.e., hepatocytes) has also resulted in chimeric animals that exhibit human drug disposition characteristics.

Therefore, animal models described herein fall into several types: (i) KO/null, (ii) humanized knock-in of gene of interest and KO of mouse gene, and (iii) chimeric. Each of these models is described in greater detail in the chapter within the context of drug metabolism, nuclear transcriptional factors, and drug transporters.

For DMEs, GEMA models for phase I and II enzyme families have been reported, and salient features of the models used to elucidate roles, mechanisms, and toxicities are reviewed. In a number of studies using GEMA models, implications for new insights into disease states or drug development are also discussed. Models for phase I enzymes pertaining to cytochrome P450 families (CYP1A, CYP2D6, CYP2E1, and CYP3A), epoxide hydrolases (EHs) (soluble and microsomal), aldehyde oxidase, monoamine oxidase (A and B), alcohol and aldehyde dehydrogenases (ALDHs), flavin-containing monooxygenases, and cholinesterases [acetylcholinesterase (AChE) and butyrylcholinesterase (BChE)] are reviewed in this chapter, as well as the phase II enzymes uridine 5'-diphospho-glucuronosyltransferase (UDP-glucuronosyltransferase, UGT) and sulfotransferases.

A variety of GEMAs have been generated to evaluate the role of ligand-activated transcriptional factors in gene regulation for pregnane-X-receptor (PXR), constitutive androstane receptor (CAR), peroxisome-proliferator-activated receptor, farnesoid X-activated receptor (FXR), and aryl hydrocarbon receptor (AHR). The generation of GEMA models with either the mouse gene KO or human gene knock-in and multiple gene KO models provide a wide range of *in vivo* tools to evaluate how these transcriptional factors work individually or in concert to regulate the expression of specific genes that control the differentiation, development, homeostasis, and metabolism of organisms.

Drug transporters are an evolving field with many proteins involved in the distribution of drugs and endogenous substrates. Many of the GEMA models are KO animals that have facilitated the association of transporters to drug distribution across tissues and tissue barriers of the gastrointestinal tract, placenta, testes, and brain. For transporters that lack human orthologs such as the organic anion transporting polypeptide (OATP), humanized animal models are ideal for exploring the contribution of human transporters toward the pharmacokinetics and disposition of new drug entities before dosing in humans.

Overall, the intent of this chapter is to provide an overview of the variety of GEMA models available to investigate drug metabolism, pharmacokinetics, and the role of transcriptional factors involved in the regulation of genes that govern the expression of DMEs and transporters.

19.2 INTRODUCTION

The body requires a state of homeostasis such that everything coming in must go out. Perturbations in this balance results in the organism accumulating compound, in concentrations that may reach toxic levels. Absorption, distribution, metabolism, and excretion (ADME) describes the way a compound passes through the body. Most compounds are not sufficiently polar (water-soluble) to be excreted without being metabolized. For these, the body may increase water solubility through the processes of phase I or phase II metabolism. Phase I metabolism is often mediated by oxidative processes involving cytochrome P450 and flavin monooxygenase (FMO). Parent compound and metabolites can either be eliminated directly from the body through the action of transporters or undergo further metabolism by phase II conjugative enzymes such as uridine 5'-diphosphoglucuronosyltransferase (UGT), sulfotransferase (ST), or glutathione-S-transferase (GST).

There is a tremendous degree of complexity and variation between DMEs and transporters in mammalian species. As such a chemical can be metabolized to a greater extent in preclinical species such as rats and mice as compared to humans. This is true for transporters in which species differences are commonly observed in the transport of compounds. This leads to difficulties when using typical rodent models to study the metabolism, transporter and biological activities of drugs, and then extrapolating this data to humans. Considerable progress has been made in the cloning and characterization of recombinant drug-metabolizing and transport proteins to understand substrate and inhibitor specificities. Only recently have genetic studies been employed using mammalian systems to assess DME and transporter function in animals, involving either targeted disruption of specific genes, or transgenic or humanized rodent (mouse or rat) models.

There are numerous GEMA models generated for drug metabolism and transporter proteins that have provided greater characterization and mechanistic understanding of proteins that contribute to the disposition of drugs. The generation of new models is constantly evolving and expanding. The authors have focused on GEMAs that have been widely studied and acknowledge that this chapter is not inclusive of all models. Several tables have been generated, which capture the GEMA models available to study DMEs and transcriptional factors involved in the upregulation of genes and drug transporters (Tables 19.1–19.3).

19.3 NOMENCLATURE OF DIFFERENT ANIMAL MODELS

GEMA models are a useful *in vivo* tool for evaluating the functions of genes. A transgenic animal is defined as an animal in which specific sequences of DNA from another species have been incorporated into the host genome, causing a disruption which effectively eradicates the activity of the targeted gene. The modified gene is known as the *transgene*. The mouse is the typical species in which to generate transgenic animal models. Thus, a transgenic animal can be defined as one having any specific, targeted genetic modification [1]. There are several transgenic animal models available to evaluate DMEs and transporters, comprising KO/null, chimera, and humanized/knock-in models.

TABLE 19.1 Genetically Modified Animal Model and Application: Drug-Metabolizing Enzymes

Gene Target	Model	Application	Section
Cytochrome P450 1A2	CYP1A knock-out mouse model Cyp1a2 ^{-/-}	Pharmacokinetics and pharmacodynamics of 1A2 substrates degradation of bilirubin	19.4.2.1
	CYP1A humanized mouse model hCYP1A1_1A2 Cyp1a2 ^{-/-}	Pharmacokinetic and human risk assessment studies, involving any drug or environmental toxicants that are 1A2 substrates	19.4.2.2
Cytochrome P450 2D6	CYP2D6 humanized mouse model hCYP2D6Cyp2d6 ^{-/-}	Pharmacokinetics of 2D6 substrates impact of compounds on 2D6 expression hepatic and no hepatic metabolism of endogenous/exogenous 2D6 substrates	19.4.3.1
Cytochrome P450 2E1	CYP2E1 knock-out/knock-in Cyp2e1 ^{-/-} hCYP2E1	CYP2E1-induced hepatotoxicity toxicity of acetaminophen (APAP) <i>in</i> <i>vivo</i> metabolism of benzene and benzene-induced toxicity	19.4.4.1
	CYP2E1 humanized mouse hCYP2E1 Cyp2e1 ^{-/-}	Toxicity of acetaminophen (APAP) and ethanol	19.4.4.1
Cytochrome P450 3A4	CYP3A humanized mouse hCYP3A4Cyp3a ^{-/-}	Pharmacokinetics of 3A4 substrates hepatic and intestinal metabolism of 3A4 substrates	19.4.5.1
	CYP3A chimeric-HL mouse uPA ^{+/+} /SCID	Pharmacokinetics of 3A4 substrates and induction of CYP3A4	19.4.5.3
Microsomal epoxide hydrolase	Microsomal epoxide hydrolase knock-out mEH ^{-/-}	Evaluate polycyclic hydrocarbon carcinogens and detoxification pathways	19.5.1.1
mEH and sEH	Chimeric-HL mice	Chimeric-HL model described for mEH and sEH	19.5.1.2
Epoxide hydrolase soluble	Soluble epoxide hydrolase knock-out sEH ^{-/-}	Evaluate role of sEH on blood pressure and renal arachidonic acid metabolism	19.5.2.1
	Soluble epoxide hydrolase humanized mouse	Model utilized to evaluate the role of sEH in the brain in relation to cerebral blood flow and protection from ischemic injury	19.5.2.2

Aldehyde oxidase	AOX chimeric-HL mouse UPa+/+/SCID	Investigate species-dependent metabolism of <i>N</i> ¹ -methyl nicotinamide by AOX	19.6.1.1
Monoamine oxidase	MAO-A knock-out mouse Mao-A—/—	Evaluate the role of MAO-A in the detoxification and regulation of amines for normal biological function	19.6.2.1
	MAO-B knock-out mouse Mao-B—/—	Evaluate the role of MAO-B in the detoxification of neurotoxin <i>N</i> -methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)	19.6.2.2
	MAO-double knock-out mouse Mao-A/B—/—	Examine the developmental phenotypic changes when both monoamine oxidases are absent	19.6.2.3
Alcohol dehydrogenase	ADH knock-out mouse model Adh1—/—, Adh3—/—, and Adh4—/—	Investigated role of murine Adh enzymes in ethanol and retinol metabolism	19.6.3.1
Aldehyde dehydrogenase	ALDH knock-out mouse model Aldh2—/—	Investigate <i>in vitro</i> metabolism of methoxyacetaldehyde in mitochondrial fractions from Aldh2—/— mice. Evaluate inhalation toxicity of acetaldehyde. Investigate effects of subacute ethanol toxicity. Investigate effects of ethanol exposure on DNA and Cyp2E1 expression	19.6.3.2
Flavin monooxygenase	FMO knock-out mouse model Fmo1—/—	Evaluate contribution of Fmo1 to pharmacokinetics of imipramine	19.6.4.1
Acetylcholine esterase	AChE knock-out mouse model AChE—/—	Investigate role of AChE in VX toxicity. Evaluate effects of AChE-inhibiting drugs rivastigmine and donepezil on AChE levels for Alzheimer's disease therapy	19.7.1.1
Butyrylcholinesterase	BChE knock-out mouse model BCHE—/—	Investigate effects of AChE inhibitors donepezil and (–)-huperzine A in AChE and BChE—/— mice for Alzheimer's disease therapy. Evaluate toxicity of cocaine in BCHE—/— mice, wild type and heterozygotes mice	19.7.1.2

Gene Target	Model	Application	Section
UDP-glucuronyl transferase	UGT1A knock-out mouse Ugt1 ^{−/−}	Evaluate the physiological significance of Ugt in development. Evaluate the role in bilirubin metabolism and metabolism of drug	19.8.1
	UGT1A knock-in mouse Tg-UGT1	Examine the functional and regulatory properties of human UGT1A1	19.8.2
	UGT1A knock-out/knock-in mouse Tg-UGT1	Examine human-specific drug conjugation. Improve human UGT1A-dependent drug clearance	19.8.3
	UGT chimeric-HL mouse UGT1A1, UGT1A9, UGT2B7	Study human glucuronidation	19.8.4
Sulfotransferase	SULT1E1 knock-out mouse model Sult1E1 ^{−/−}	Investigate reduced fertility in Sult1E1 ^{−/−} mice due to high estrogen levels and reduced COX-2 expression	19.9.1
	Natural SULT knock-out mouse brachymorphic mouse	Investigate the bioactivation of safrole and potential carcinogens in mouse liver	19.9.2

TABLE 19.2 Genetically Modified Animal Model and Application: Induction

Gene Target	Model	Application	Section
Pregnane X receptor	PXR knock-out mouse model Pxr ^{-/-}	Evaluate the role that Pxr plays in regulation of genes (<i>CYPs</i> , <i>UGTs</i> , <i>ST</i> , <i>P-gp</i> , <i>BCRP</i> , and <i>OATPs</i>). Pharmacokinetics of drug-metabolizing and transporter proteins. Bile salt regulation	19.10.1
	PXR humanized mouse model hPXR ^{Pxr} ^{-/-}	Evaluate the role of human PXR in regulation of drug-metabolizing and transporter genes and these genes in disease states. Pharmacokinetics of drug-metabolizing and transporter proteins	19.10.1.1
Constitutive androstane receptor	CAR knock-out mouse model Car ^{-/-}	Evaluate the role that Car plays in regulation of genes (<i>CYPs</i> , <i>UGTs</i> , <i>GST</i> , <i>MRPs</i> , and <i>OATPs</i>). Pharmacokinetics of drug-metabolizing and transporter proteins. Regulation of bilirubin homeostasis. Role in metabolic disorders	19.10.2.1
	CAR humanized mouse model hCAR ^{Car} ^{-/-}	Evaluate the role that human CAR plays in gene regulation (<i>CYPs</i> , <i>UGTs</i> , <i>GST</i> , <i>MRPs</i> , and <i>OATPs</i>)	19.10.2.2
Peroxisome-proliferator-activated receptor	PPAR knock-out mouse Ppar ^α ^{-/-} , Ppar ^{β/δ} ^{-/-} , Ppar ^γ ^{-/-}	Investigate role in control of CYP2B family in bioactivation of carcinogens. Evaluate PPARs' role in lipid metabolism, glucose homeostasis, and adipocyte differentiation and inflammation	19.10.3.1
	PPAR humanized mouse hPPAR ^α ^{Pparα} ^{-/-}	Evaluate species differences and role of human PPAR ^α in regulating CYP4A in starvation, diabetes, and fatty acid metabolism	19.10.3.2

(continued overleaf)

TABLE 19.2 *(continued)*

Gene Target	Model	Application	Section
Farnesoid-X-activated receptor	FXR knock-out mouse Fxr ^{-/-}	Evaluate role in regulation of bile acids, lipid, and glucose homeostasis	19.10.4.1
Pregnane X receptor and constitutive androstane receptor	Combination models hPXRCar ^{-/-} , hCARPxr ^{-/-} , Pxr ^{-/-} Car ^{-/-} , hPXRhCAR	Evaluate cross talk between PXR and CAR in gene regulation, determine which genes require both or only one transcriptional factor	19.10.5
Aryl hydrocarbon receptor	Ahr knock-out model Ahr ^{-/-}	Investigate regulation of P450 enzymes involved in bioactivation of aryl hydrocarbon aromatic carcinogens. Role of enzymes involved in reactive metabolite formation	19.10.6.1
	AHR humanized mouse hARHArh ^{-/-}	Investigate human AHR-induced gene response in the presence of toxins	19.10.6.2
	AHR chimeric mouse	Rat <i>Ahr</i> gene contains mutation rendering it TCDD resistant. Enables mechanistic evaluation of Ahr-mediated toxicities	19.10.6.3

19.3.1 Knock-Out (Null) Models

The original pioneering work in developing techniques for generating transgenic KO animals was done by Mario Capecchi, Martin Evans, and Oliver Smithies, who were recognized with the Nobel prize in “Medicine or Physiology” in 2007. The production of a null/KO animal model (Fig. 19.1) involves isolating ES cells from a male brown mouse with a normal gene [2–4]. A copy of the mutated gene containing

Figure 19.1 Diagram to construct knock-out animal model. (See color insert.)

a drug resistance marker gene such as phosphoglycerine kinase-neomycin (PGK-neo) is inserted into a selected region of the cDNA, generally downstream from the mouse promoter enhancer sequence of the target gene. The transgene is then isolated from the plasmid of the vector and microinjected into the pronuclei of white fertilized mouse eggs. The addition of *PGK-neo* disrupts normal gene expression. The altered DNA sequence will undergo homologous recombination to incorporate the altered target gene with the PGK-neo cassette into the mouse genome. By transplanting stem cells containing the inactive target gene into a white mouse embryo, a chimeric animal is formed that has regions of cells that grew from white mouse cells and regions that grew from brown stem cells. Some of the cells that have the inactive target gene may develop into reproductive cells. The germline chimeras are easy to identify because they have both brown and white patches on their fur. Among the offspring, half will be brown containing a copy of the inactive gene in all their cells. These mice have one normal and one inactive copy of the target gene. The heterozygote mice [identified by polymerase chain reaction (PCR)] are then bred. A quarter of the offspring will have two copies of the “knocked out” or inactive target genes.

19.3.2 Humanized Mouse (Knock-In and Knock-In/Knock-Out Mouse)

The formation of a humanized mouse follows similar cloning and isolation procedures as that used to make the KO mouse (Fig. 19.2). The human cDNA of the target gene is isolated and cloned downstream of the liver-specific mouse promoter/enhancer sequence in a plasmid vector. The transgene is then isolated and microinjected into the pronuclei of fertilized mouse eggs. The injected eggs are transplanted into the oviduct of a female KO target gene mouse. The KO mouse will lack the species target gene, enabling only the ortholog human gene to be expressed, this mouse is called *knock-in/knock-out*. However, if the human transgene is injected into the oviduct of a female normal mouse, the offsprings will contain both endogenous and human transgene, it is simply called a *knock-in*. The mice are screened by PCR to identify individuals carrying the human gene.

19.3.3 Chimeric-HL

19.3.3.1 (*uPA*+/*+/SCID*) Mouse. A single animal organism with genetically distinct cells from two different zygotes is commonly referred to as a *chimera*. Chimeric mice with partially humanized liver were first described in 2001 and for purposes of this chapter will be referred to as *chimeric-HL*. The animals generated were immunodeficient transgenics that express urokinase-type plasminogen activator (uPA) under the transcriptional control of an albumin promoter, rendering it hepatotoxic. Dandri *et al.* [5] reported that the liver (uPA)/recombinant activation gene-2 mice could be repopulated by ~15%, with human hepatocytes. Similarly, Mercer *et al.* [6] then showed a liver portion in *uPA*+/*+/SCID* mice could be repopulated with human hepatocytes. Given that these studies were used to investigate the hepatitis virus, a low replacement value was likely to be sufficient to achieve their purposes. In contrast, studies for human ADME would necessitate a higher degree of repopulation.

In this regard, Tateno *et al.* [7] generated chimeric-HL *uPA*+/*+/SCID* mice, in which the mouse livers could be replaced to more than 90% with human hepatocytes. The *uPA*+/*+/SCID* mice at 20–30 days after birth were injected with human

Figure 19.2 Diagram to construct knock-in/knock-out animal model. (See color insert.)

hepatocytes. Repopulation levels were estimated by determining the concentration of human serum albumin (hAlb). Levels were found to reach around 5 mg/mL after 60 days posttransplantation. The presence of human hepatocytes in the chimeric livers was also confirmed by taking liver sections and subjecting them to human-specific cytokeratin 8/18 (hCK8/18), an antibody that reacts specifically with human hepatocytes and bile duct cells, but not with those of the host mice. Given that hepatocytes from various donors and cryopreserved hepatocytes could be used to generate such chimeric-HL mice, interindividual variability in the pharmacokinetics and toxicity of drugs can potentially be evaluated.

19.3.3.2 Chimeric-HL (*Fah*^{-/-}/*Rag2*^{-/-}/*Il2rg*^{-/-}) Mouse. Despite engraftment levels of up to 70% having been reported in uPA-expressing animal models, the system has several major disadvantages that have prevented its widespread use. These include poor breeding efficiency, a narrow time window for transplantation, and renal disease in repopulated mice [7]. In order to provide a broadly useful hepatic xenorepopulation system, Azuma *et al.* [8] have recently generated an immunodeficient strain of mice

deficient in the tyrosine catabolic enzyme fumarylacetoacetate hydrolase (*Fah*). *Fah* mutant mice, which develop liver disease only when the protective drug 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC) is withdrawn, have proven to be a reliable model of liver repopulation with transplanted cells [9,10]. The authors showed that their severely immunodeficient mice triply mutant for *Fah* (this gene encodes the last enzyme in the tyrosine catabolism pathway), *Rag2* (the recombination activating gene encodes enzymes that play an important role in the rearrangement and recombination of the genes of immunoglobulin and T-cell receptor molecules), and the common γ -chain of the interleukin receptor (FRG) could, after pretreatment with a urokinase-expressing adenovirus, be highly engrafted (up to 90%) with human hepatocytes from multiple sources, including liver biopsies. Furthermore, human cells could be serially transplanted from primary donors and repopulate the liver for at least four sequential rounds. Using standard drug metabolism assays, the authors reported that the hepatocytes from repopulated FRG livers were indistinguishable from normal human adult hepatocytes.

19.4 CYTOCHROME P450

19.4.1 Cytochrome P450

It has been well documented that approximately two-thirds of the marketed drugs are metabolized by members of the CYP superfamily, in particular the subfamilies: CYP1, CYP2, and CYP3 [11]. Model systems in which genes from cytochrome P450s have been deleted or inactivated have great potential to further our understanding of the function of these enzymes.

Given the complexity of genes that encode DMEs and their overlapping substrate specificities, there is a significant challenge when it comes to analyzing KO experiments, since loss of a single enzyme may be partially or completely compensated by one or more remaining enzymes. Furthermore, the widespread distribution of genes such as those for cytochrome P450s throughout the genome makes their collective obliteration technically unfeasible, at least with current technology. This creates potential problems in the interpretation of phenotypes and in delineation of the function of individual enzymes.

With respect to cytochrome P450 genes, a number of them have been deleted over the past decade or so. These can be divided into two types: (i) those with no overt phenotype, which tend to result from the deletion of P450s involved in xenobiotic metabolism and (ii) those where inactivation of P450s that undertake essential “housekeeping” functions, that is, CYP19 (aromatase) and CYP7A (cholesterol 7 α -hydroxylase) [12,13], results in a phenotypic change, normally embryonic lethality or perinatal morbidity. Henderson *et al.* [14] have recently argued that a more informative approach might be to delete several or all P450s simultaneously, which could be achieved by deletion of cytochrome P450 reductase (CPR), the sole electron donor to microsomal P450 enzymes. However, as indicated above, given the reported lethality following deletion of individual P450s involved in cholesterol or steroid hormone biosynthesis, complete deletion of all P450 function would not be the most pragmatic approach [15]. This embryonic lethality was circumvented via Cre/loxP technology, which selectively deletes liver CPR [14]. Although lacking hepatic CPR and hence completely devoid of liver P450 function, these mice (Hepatic Reductase Null, HRNTM

mice) were both viable and fertile [16]. As such it was argued that this model has the potential to be a valuable tool in drug development, in assessing the role of hepatic CYPs in drug bioavailability and efficacy [17,18]. In contrast, if a CYP responsible for xenobiotic metabolism is deleted, it is not a concern, at least in the absence of an appropriate chemical challenge. The following sections summarize information from the literature on the application of GEMA models in the assessment of the P450 enzymes: CYP1A, CYP2D, CYP3A, and CYP2E.

19.4.2 CYP1A

CYP1A family consists of CYP1A1, CYP1B1, and CYP1A2. CYP1A2 is the major P450, accounting for 10% of hepatic P450s. In contrast, CYP1A1, also known as *aryl hydrocarbon hydroxylase* (ARH), is mainly expressed in lung, placenta, and lymphocytes, albeit in a much lesser abundance. Both CYP1A1 and CYP1A2 are inducible on exposure to xenobiotics, such as 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), 3-methylcholanthrene (3-MC), polycyclic aromatic hydrocarbons (PAHs), and polychlorinated biphenyls [19]. Both P450s are primarily involved in the metabolic activation of procarcinogens, such as arylamines, PAHs, and heterocyclic amines [19], the latter being produced during the cooking of meats and fish, with the most abundant being 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine (PhIP). Metabolic activation of PhIP is principally mediated by CYP1A2. Increased activity of CYP1A2 in combination with higher *N*-acetyltransferase activity has been associated with an elevated risk for colon cancer in individuals eating well-cooked meats [20]. Species differences in the oxidative metabolism of PhIP between humans and rodents [21] make extrapolation of potential cancer risk from experimental animals to humans difficult. However, by generating humanized mouse lines, suitable models can be provided for human health risk assessment studies of PhIP, as well as other dietary or environmental toxicants. These models have been also been applied by researchers investigating the potential disposition of drugs that are substrates for CYP1A1 or CYP1A2.

19.4.2.1 CYP1A Knock-Out Mouse Model. The *Cyp1a2*^{-/-} mice have been used to demonstrate the role of CYP1A2 in the pharmacokinetics and pharmacodynamics of the muscle relaxant zoxazolamine [22], where a ninefold decrease in enzyme activity was observed in the *Cyp1a2*^{-/-} mice. The wild-type (WT) and *Cyp1a2*^{-/-} mice have also been used to study the pharmacokinetics of caffeine [23]. The half-life of caffeine elimination from blood was about seven times longer in the *Cyp1a2*^{-/-} mice than in the WT mice, while the elimination clearance was eight times slower in the *Cyp1a2*-deficient mice compared to that in the WT mice. Theophylline pharmacokinetics has also been studied in WT and *Cyp1a2*^{-/-} KO mice [24]. Theophylline clearance was estimated as being 10 and 2.5 mL/min/kg for WT and *Cyp1a2*^{-/-} KO mice, respectively, with corresponding half-lives of 40 and 172 min.

Cyp1a2^{-/-} KO mice have also been used to demonstrate the involvement of CYP1A2 in microsomal degradation of bilirubin [25]. Previous studies have shown that liver microsomes from animals administered β -naphthoflavone (BNF) or 3-MC had increased activity for bilirubin degradation compared to microsomes from uninduced animals and that this rate could be increased further when a coplanar halogenated molecule, such as 3,4,39,49-tetrachlorobiphenyl (TCB), was added to the microsomal incubation together with NADPH [26]. It was also reported that CYP1A1 was

responsible for catalyzing bilirubin degradation by induced rat liver microsomes in the presence of TCB. However, Zaccaro *et al.* [25] used Cyp1a2 (2/2) mutant mice to investigate (i) the relative roles of Cyp1a2 and Cyp1a1 in bilirubin degradation and (ii) whether Cyp1a2 and Cyp1a1 require TCB addition for bilirubin-degrading activity. In WT mice, 3-MC treatment caused a threefold increase in the rate of bilirubin degradation. TCB caused a small but significant increase in bilirubin degradation. In Cyp1a2 (2/2) mutant mice, there was no MC-induced increase in microsomal bilirubin degradation in the absence of TCB. However, addition of TCB caused a three- to fivefold increase in bilirubin degradation in these mice. The authors concluded that CYP1A2 was responsible for microsomal bilirubin degradation in the absence of TCB and that TCB was required for bilirubin degradation by CYP1A1. This observation suggests that manipulation of CYP1A2 may be of therapeutic benefit in patients with these diseases of bilirubin conjugation.

19.4.2.2 CYP1A Humanized (Knock-In/Knock-Out) Mouse Model. Pharmacokinetics of theophylline has been evaluated in the WT, Cyp1a2^{-/-}, and humanized hCYP1A1_1A2 Cyp1a2^{-/-} mice [24]. Without the TCDD treatment, theophylline clearance values were 10, 2.8, and 4.5 mL/min/kg for the WT, Cyp1a2^{-/-}, and hCYP1A1_1A2 Cyp1a2^{-/-} mice, respectively. Following TCDD treatment, a 3.5-fold increase in theophylline clearance was observed in the WT mice, compared to 1.8-fold in the humanized CYP1A1_1A2 Cyp1a2^{-/-} mice. However, no change in the clearance was seen in Cyp1a2^{-/-}. These data are consistent with the metabolism of theophylline being mediated by mouse Cyp1a2 as well as human CYP1A2. Toxicokinetics of benzo[a]pyrene (B[a]P) studied in five mouse lines, WT, Cyp1a1^{-/-}, Cyp1a2^{-/-}, Cyp1a1/1a2^{-/-}, and CYP1A1_1A2 Cyp1a1/1a2^{-/-} [27], showed plasma steady-state levels of 1.3, 29, 0.51, 62, and 0.8 ng/mL, respectively. This together with corresponding plasma alanine transaminase (ALT) and aspartate transaminase (AST) suggest that both human CYP1A1 and mouse Cyp1a1 are important in metabolism of oral B[a]P.

Shi *et al.* [28] recently discussed an hCYP1A1_1A2_Cyp1a1/1a2^{-/-}_Ahrd mouse model generated, following the breeding of CYP1A1_1A2_Cyp1a1/1a2^{-/-}_Ahrb1 mice with B6.D2-Ahrd congenic mice. In this humanized model, human CYP1A1 and CYP1A2 are controlled by the endogenous mouse high affinity AHR in the hCYP1A1_1A2_Cyp1a1/1a2^{-/-}_Ahrb1 line and by the endogenous mouse poor affinity AHR in the hCYP1A1_1A2_Cyp1a1/1a2^{-/-}_Ahrd line. The humanized lines were characterized by quantifying human CYP1A messenger RNA (mRNA) levels in liver, lung, and kidney, as a function of four doses of the potent inducer, TCDD. Maximally induced mRNA levels of mouse Cyp1a1 were described as ~10 times higher than those of human CYP1A1; in contrast, maximally induced mRNA levels of mouse Cyp1a2 were less than twofold higher than those of human CYP1A2 in liver. They also reported that maximally induced mRNA levels of human CYP1A2 in liver were ~12 times higher than those of human CYP1A1, whereas maximally induced mRNA levels of mouse Cyp1a2 were ~threefold greater than those of mouse Cyp1a1. It was argued that the newly developed hCYP1A1_1A2_Cyp1a1/1a2^{-/-}_Ahrd line complemented their previously described hCYP1A1_1A2_Cyp1a1/1a2^{-/-}_Ahrb1 line, for use in carrying out pharmacokinetic and human risk assessment studies, involving any drug or environmental toxicant that is an effective substrate for CYP1A1 or CYP1A2.

Uno *et al.* [29] questioned the physiological relevance of these human mRNA levels in the intact mouse and whether these humanized mouse lines actually reflect average *CYP1A1* and *CYP1A2* gene expression that might be expected among individuals in a human population or was the expression too low or high? They compared basal and dioxin-induced CYP1A mRNA copy numbers, protein levels, and enzyme activity from four enzymes (benzo[a]pyrene hydroxylase, ethoxyresorufin-*O*-deethylase, acetanilide-4-hydroxylase, and methoxyresorufin-*O*-demethylase) in livers from hCYP1A1_1A2_Cyp1a1/1a2-/-_Ahr^d and uPA/SCID chimeric mouse line carrying human hepatocytes. In contrast to the findings from Shi *et al.* [28], Uno *et al.* [29] reported a mouse/human-induced CYP1A1 ratio of ~0.03 and a mouse/human-induced CYP1A2 ratio of ~4. Moreover, the mRNA levels of human CYP1A2 in the liver compared to those of human CYP1A1 was only 0.13, while that between maximally induced mRNA levels of mouse CYP1A2 and CYP1A1 was approximately threefold. It was argued that this inconsistency in the calculated ratios reflects the disparity between the “relative values” by Shi *et al.* [28] and their “absolute values” (i.e., copy numbers per microgram total RNA) in this study.

The procarcinogen PhIP is the most abundant heterocyclic amine formed during the cooking of foods. Metabolism of PhIP by CYP1A2 differs substantially between humans and rodents, with more N2-hydroxylation (activation) and less 4'-hydroxylation (detoxication) in humans. Thus, given that the human response to PhIP and potentially other heterocyclic amine exposure may not be accurately reflected in standard laboratory rodents, Cheung *et al.* [30] studied species differences in heterocyclic amine metabolism using two transgenic mouse lines: one expressing the human CYP1A1 CYP1A2 transgene in a mouse Cyp1a1-null background (hCYP1A1) and another expressing human CYP1A1 CYP1A2 in a mouse Cyp1a2-null background (hCYP1A2). Differences in the metabolism of the heterocyclic amine PhIP were observed between WT and hCYP1A2 mice. Moreover, PhIP was preferentially metabolized by N2-hydroxylation in hCYP1A2 mice, whereas in WT mice, 4'-hydroxylation was the predominant pathway. This confirms earlier work [31] that first showed the human CYP1A2 preference for N2-hydroxylation relative to 4 α -hydroxylation (ratio of 97:1) compared with the mouse ratio of 1.7:1 for these pathways. These results highlight the potential effectiveness of using these transgenic, humanized mice as models for determining human health risks to PhIP and other heterocyclic amines instead of WT mice.

19.4.3 CYP2D6

CYP2D isozymes have been identified in many mammalian species and are involved in oxidation of various xenobiotics and drugs. In humans, the only functional gene is *CYP2D6*, while *CYP2D7p* and *CYP2D8p* are two inactive pseudogenes [32]. In contrast, mice have at least nine *CYP2D* genes, *Cyp2d9–2d13*, *Cyp2d22*, *Cyp2d26*, *Cyp2d34*, and *Cyp2d40*, and rats have six *CYP2D* genes: *Cyp2d1–2d5* and *Cyp2d18* [33]. Given this degree of diversity, it is not surprising that marked species differences exist in CYP2D metabolism between humans and rodent. For humans, understanding metabolism via CYP2D6 is particularly important as it has been shown to be involved in the metabolism of more than 20% of prescribed drugs, most of which act in either the heart or central nervous system (CNS) [34]. As important is the fact that it is polymorphically expressed resulting in three distinct human phenotypes, namely poor metabolizers (PMs), who lack the functional enzyme; extensive metabolizers

(EMs); and ultrarapid metabolizers (UMs). The most common phenotyping procedure of CYP2D6 is the determination of the metabolic ratio (MR) of debrisoquine (DEB)/4-hydroxy debrisoquine (as measured in the urine). In PMs, MR values greater than 12.6 are seen, while values less than 12.6 are seen in EMs. Individuals with an MR value much less than 0.1 are referred to as *UMs* [35]. To overcome the species difference in CYP2D metabolism, a number of GEMA have been established and are discussed below.

19.4.3.1 CYP2D6 Humanized (Knock-In) Mouse Model. Corchero *et al.* [36] first established homozygous and heterozygous CYP2D6 humanized mice models. After a single oral dose of DEB (2.5 mg/kg), both CYP2D6 heterozygous and homozygous mice had DEB serum levels significantly lower than in WT. Consistently, 4-hydroxy debrisoquine (4-OH-DEB) levels are highest in CYP2D6 homozygous, intermediate in CYP2D6 heterozygous, and extremely low in the WT mice. In addition, the pharmacokinetic data showed the DEB area under the curve (AUC) to be three- and sixfold higher in WT mice than in heterozygous and homozygous CYP2D6 humanized mice, respectively, reflecting differences in the elimination half-life of DEB, which was 2.1 and 1.4 times shorter in the heterozygous and homozygous CYP2D6 humanized mice than in WT mice. Accordingly, CYP2D6 humanized mice showed a clearance six- and fourfold higher than WT mice. On the basis of the urinary recovery data, the MR was estimated to be 10 for the WT mice and 0.5 for the CYP2D6 humanized mice. Interestingly, the MR of DEB in the WT mice was similar to that in human PMs, while the MR of DEB in humanized CYP2D6 mice was close to that in human EMs.

Work from the same group also looked at the role played by the transcriptional factor, hepatic nuclear factor 4 α (HNF4 α) [36], which had previously been shown to regulate the expression of *CYP2D6* gene *in vitro* [37]. A humanized mouse line carrying the human *CYP2D6* gene and the HNF4 α conditional mutation was created by cross-breeding the humanized CYP2D6 mice with an HNF4 α conditional null mouse line to investigate the effect of this transcriptional factor on the CYP2D6 expression *in vivo*. Disruption of HNF4 α expression resulted in a twofold decrease in the expression of CYP2D6 enzyme. Moreover, the metabolism of DEB was significantly reduced in the humanized CYP2D6 mice lacking HNF4 α gene. The urinary recovery was 7.2% of dose for 4-hydroxylated DEB in the humanized CYP2D6 mice carrying HNF4 α gene. In the absence of HNF4 α gene, the urinary recovery was only 2.9%. On the basis of the urinary recovery data, the MR was estimated to be 2.6 and 3.6, respectively, in the humanized CYP2D6 mice carrying HNF4 α gene and those lacking HNF4 α gene.

This model has been further validated as a model for CYP2D6 [38]. The expression of human CYP2D6 and mouse CYP2D enzymes in these humanized and WT mice were quantified by immunoblotting and detected at the cellular level by immunocytochemistry. In humanized mice, the cell-specific expression of CYP2D6 in liver, kidney, and intestine was similar to those reported in humans. Human CYP2D6 was not detected in the brain of transgenic mice, while mouse CYP2D proteins were present. This has been observed before in a transgenic CYP3A4 mouse model, where this protein is expressed in intestine but not in liver [39], a site of high expression levels in humans. Miksys *et al.* [38] concluded that the transgenic mouse model is useful when investigating CYP2D6-mediated metabolism in liver, kidney, and especially the intestine, where expression patterns demonstrated substantial species differences.

Cytochrome P450 2D6 is known to be absent from the liver and brain for a small percentage (~10%) of the population [40], but its function in the human brain remains elusive even though personality differences have been reported between EMs and PMs, suggesting the potential existence of endogenous substrates for CYP2D6 [41]. To address this, the CYP2D6-humanized mouse model has been further applied to the search for potential endogenous substrates for CYP2D6 [42–44]. *Ex vivo* studies using microsomes from these humanized mice showed that CYP2D6 catalyzed the O-demethylation of a number of psychotropic methoxyindolethylamines derived from serotonin (5-hydroxytryptamine, 5-HT) [42,43,45]. In this regard, Yu *et al.* [43] established that 5-methoxytryptamine (5-MT), a metabolite and precursor of melatonin, was a specific and high turnover endogenous substrate of CYP2D6. After the intravenous (IV) coadministration of 5-MT and pargyline [to protect against monoamine oxidase A (MAO-A) metabolism], serum 5-HT levels were approximately threefold higher in CYP2D6-transgenic mice than WT mice. The authors postulated that this regeneration of 5-HT from 5-MT provided the missing link in the serotonin–melatonin cycle. Interestingly, following coadministration of pargyline and 5-MT, all the mice exhibited tremors, although CYP2D6-transgenic mice appeared less pronounced than the WT. Such tremors were thought to result from dramatically elevated serum 5-MT levels. The authors suggested that caution be taken when using 5-MT (as mood enhancer) with MAO inhibitors in humans, especially in CYP2D6 PMs. More recently, WT and humanized CYP2D6 mice have been used to investigate the metabolism of 5-methoxy-*N,N*-dimethyltryptamine (5-MeO-DMT) [46], a natural psychoactive indolealkylamine drug that has been used for recreational purposes [47]. Previous *in vitro* studies have shown that bufotenine, the major metabolite of 5-MeO-DMT, is produced by CYP2D6 [45]. Following the administration of a high dose of 5-MeO-DMT, humanized CYP2D6 mice showed significantly higher systemic exposure (AUC) to the active metabolite bufotenine than WT mice. As humanized CYP2D6 mice differ from WT mice in the expression of functional CYP2D6 enzyme, these findings have prompted the expectation that subjects with regular or increased CYP2D6 activity would have more complex drug effects induced by bufotenine metabolite.

In light of the fact that 5-MeO-DMT is predominantly inactivated by MAO-A, coabuse with MAO inhibitors such as harmaline (one of the major psychotropic ingredients in recreational beverage *Ayahuasca* [48]) would likely elicit a metabolic drug interactions (DDI) and increase the risk of 5-MeO-DMT intoxication. Studies have shown that pretreatment of harmaline led to a prolonged residual time within the body (referred to by the *mean residence time*, MRT) and increased AUC in humanized CYP2D6 mice [46,49]. Together, their observations in humanized CYP2D6 mice suggested that MAO inhibitors and CYP2D6 status may have significant impact on 5-MeO-DMT metabolism and pharmacokinetics as well as the formation of bufotenine. As such the model allowed novel insights toward biochemical determinants in 5-MeO-DMT pharmacokinetics and harmaline-5-MeO-DMT DDI, and further advanced understanding of risks in 5-MeO-DMT intoxication.

19.4.4 CYP2E1

Cytochrome P450 2E1 is predominately expressed in human liver, with some lower level extrahepatic expression in the kidney, lung, and brain. A number of genetic polymorphisms have been described for the human *CYP2E1* gene, with ethnic differences

demonstrated between European and Japanese populations [50]. CYP2E1 has been found to be involved in the oxidative metabolism of a small range of substrates (mostly small polar molecules). Furthermore, it has also been shown to be a key enzyme in the metabolism and can activate numerous toxicologically important chemicals such as acetone, ethanol, benzene, halothane, and carbon tetrachloride as well as clinically used drugs as acetaminophen (APAP), disulfiram, chlorzoxazone, and carcinogens, such as the low molecular weight nitrosamines [51–54]. Before establishing CYP2E1 GEMAs, the majority of studies on its pharmacological and biochemical actions was conducted in rodents, rabbits, and cultured hepatocytes.

19.4.4.1 CYP2E1 (Knock-Out/Knock-In) Mouse. Lee *et al.* [55] first reported the production of mice homozygous for the disrupted allele, designated *Cyp2e1*^{–/–}. The authors confirmed the complete absence of protein and mRNA expression in the livers of *Cyp2e1*^{–/–} mice. Using this animal model, they went on to show how CYP2E1 influences the toxicity of APAP (also known as *paracetamol*), an over-the-counter analgesic and antipyretic that is commonly used worldwide as a substitute for acetylsalicylic acid (Aspirin®) due to its lack of gastric ulceration and general low toxicity when used within the recommended dose range [56]. Compared to WT mice, *Cyp2e1*^{–/–} mice survived up to doses of 400 mg/kg, whereas this dose was lethal in 50% of WT animals. At all doses, levels of creatinine, bilirubin, and alkaline phosphatase were within the normal range and were not significantly different between the *Cyp2e1*^{–/–} and WT mice. In contrast, liver enzymes aspartate aminotransferase and alanine aminotransferase (considered as measures of liver cell death) were elevated at high doses of APAP but were unchanged at higher doses in the *Cyp2e1*^{–/–} mice. Together these data indicated that liver damage due to formation of a reactive metabolite is involved in mediating the toxicity of APAP. CYP2E1 metabolizes APAP to a highly reactive metabolite, *N*-acetyl-*p*-benzoquinone imine, which can covalently bind to cellular nucleophiles, such as DNA, RNA, and proteins. *N*-Acetyl-*p*-benzoquinone imine is typically inactivated by glutathione-*S*-transferase (GST) [57]; however, in an overdose of APAP, the amount of the reactive intermediate metabolite formed depletes hepatic glutathione (GSH) levels, overwhelming this detoxification pathway.

This model has also been used to investigate the involvement of CYP2E1 in the *in vivo* metabolism of benzene and in the development of benzene-induced toxicity. For the metabolism studies, male *Cyp2e1*^{–/–} and WT control mice were exposed to benzene, along with a radiolabeled tracer dose of [¹⁴C]benzene. Total urinary radioactivity and all individual radiolabeled metabolites were reduced in the urine of *Cyp2e1*^{–/–} mice compared to WT controls. This tissue radioactivity analysis demonstrated that CYP2E1 was the major determinant of *in vivo* benzene metabolism and benzene-induced myelotoxicity in mice. Together, these results suggest that *Cyp2e1*-null mice can be used as a tool to screen for potential CYP2E1-induced hepatotoxicity of drug candidates by comparing with the WT mice. In fact, toxicities associated with carbon tetrachloride [58], chloroform [59], methacrylonitrile [60,61], acrylamide [60,61], and trichloroethylene metabolism [62] have all been shown using this animal model.

The transgenic model reported by Morgan *et al.* [63] (see above) still retained host expression of CYP2E1. To establish a true humanized model, transgenic mice were generated using a bacterial artificial chromosome (BAC) clone containing the entire human *CYP2E1* gene, and these were bred into a mouse *Cyp2e1*-null background, thus creating CYP2E1 humanized mice [64]. Using this mouse model, the functional

differences between human and mouse hCYP2E1 Cyp2E1^{-/-} were directly compared. Human CYP2E1 protein and mRNA expression were expressed at high levels in the liver of CYP2E1-humanized mice, with the human CYP2E1 mRNA additionally detected in some extrahepatic tissues such as kidney, small intestine, and lung, consistent with the distribution pattern reported in humans [65]. Human CYP2E1 activity was demonstrated in the livers of CYP2E1-humanized mice by the increased chlorzoxazone 6-hydroxylation (commonly used to assess human CYP2E1 activity) [50] and increased *p*-nitrocatechol formation compared with the level in Cyp2e1^{-/-} mice. Further studies showed induction of CYP2E1 in the CYP2E1-humanized mice using the known inducer acetone.

Cheng and colleagues [64] went on to investigate the effect of APAP on the WT, Cyp2e1^{-/-}, and CYP2E1-humanized mice. At a dose of 400 mg/kg APAP, liver necrosis was detected in WT but not Cyp2e1^{-/-} mice, consistent with previous studies [55]. At this dose, CYP2E1-humanized mice were found to have moderate-to-severe liver necrosis, whereas in WT mice, moderate liver necrosis was identified. However, the serum ALT levels were elevated to approximately the same levels in both WT and CYP2E1-humanized mice treated with 400 mg/kg APAP, indicating a similar toxic response. It was suggested that the current model could also provide a more conclusive answer to the role that CYP2E1 plays in ethanol toxicity, since the model used by Morgan *et al.* [63] also contained endogenous mouse Cyp2e1.

19.4.5 CYP3A

The human CYP3A subfamily consists of four members: CYP3A4, CYP3A5, CYP3A7, and CYP3A43. Among them, CYP3A4 is the most abundant hepatic and intestinal CYP enzyme in humans, accounting for 30% and 70% of total CYP, respectively, and catalyzes the metabolism of over 50% of drugs that are clinically used [66]. In mice, at least six CYP3A isoforms have been identified: Cyp3a11, Cyp3a13, Cyp3a16, Cyp3a25, Cyp3a41, and Cyp3a44 [33]. Additionally, there are at least six CYP3A isozymes identified in the rat: Cyp3a1, Cyp3a2, Cyp3a9, Cyp3a18, Cyp3a23, and Cyp3a62 [33]. Like that of other P450s, the species differences in the expression pattern of different CYP3A isozymes and their intrinsic enzyme activity between humans and rodents makes the extrapolation of drug metabolism from animals to humans quite difficult. To address this difference, various GEMA models have been established to aid the understanding of drug metabolism by this isozyme.

19.4.5.1 CYP3A Humanized (Knock-In) Mouse. Mice expressing human CYP3A4 (designated hCYP3A4) were first reported by Granvil *et al.* [39]. To generate these mice (hCYP3A4), the BAC *CYP3A4* gene, including the upstream PXR-binding sites, was microinjected into a fertilized mouse egg. IV and oral pharmacokinetics of midazolam have been studied in both the WT and hCYP3A4 mice [39]. The IV data showed no significant differences in half-life and clearance of midazolam between WT and hCYP3A4 mice. In contrast, there were significant differences in the pharmacokinetics of midazolam between the WT and hCYP3A4 mice after oral administration. The high metabolic clearance of midazolam in the hCYP3A4 mice was supported by the fact that the AUC of 1'-OH midazolam (a major metabolite of midazolam) was higher in the hCYP3A4 mice compared with WT mice. Moreover, the potent CYP3A4

inhibitor ketoconazole markedly lowered the rate of midazolam metabolism and elimination when coadministered orally with midazolam, as compared with midazolam mono-treatment. Possible explanations postulated to explain the disparity between these inhibitory effects include greater first-pass metabolism in hCYP3A4 mice, potential differences in the affinity for midazolam and ketoconazole between hCYP3A4 and mouse CYP3a proteins, and differences in tissue expression pattern for CYP3A4 and Cyp3a proteins in the mice. In this regard, Granvil *et al.* [39] measured CYP3A4 expression in hCYP3A4 mice and found it to be highly expressed in the small intestine, but surprisingly, no expression was found in the liver, despite it being the major tissue of CYP3A4 expression. The predominate expression of human CYP3A4 in the intestine but not in liver explains the lack of pharmacokinetic difference between hCYP3A4 mice and WT following IV dosing. In contrast, Cyp3a proteins were highly expressed in the liver of WT mice and to a lesser extent in the small intestine. Subsequent studies using mice generated from a BAC clone, which contains both *CYP3A4* and *CYP3A7* genes [67], revealed constitutive CYP3A4 expression in the livers of immature male and adult female mice, indicating that the transgene is developmentally regulated in a gender-specific manner [67,68]. However, the level of CYP3A4 in the adult female liver was still substantially lower than that in the small intestine. Gender-specific regulation of P450s has been extensively studied in rodents and is suggested to be attributed to differences in growth hormone secretory patterns between males and females [69]. Continuous infusion of growth hormone to mimic female secretory patterns has been shown to convert the male growth hormone secretory pattern to that of the female pattern in hCYP3A4 mice [67].

19.4.5.2 CYP3A Humanized (Knock-In/Knock-Out) Mouse. To address some of the limitations with the aforementioned hCYP3A4 mouse model, which exhibited poor hepatic CYP3A4 levels, van Herwaarden *et al.* generated and characterized transgenic mice with functional expression of human CYP3A4 cDNA in the liver, moderate levels in kidney, but not in small intestine [70]. Using midazolam and cyclosporin A to test functional activity of liver CYP3A4, the authors showed that midazolam plasma AUC concentrations decreased in the transgenic mice compared with WT. Similarly, following IV administration of cyclosporin A, CYP3A4 transgenic mice displayed reduced plasma AUC compared with WT. Yet the major disadvantage of these aforementioned hCYP3A4 mice models is the coexpression of mouse Cyp3a. To address this, the same group generated two strains of Cyp3a KO mice lacking all functional murine *Cyp3a* genes (*Cyp3a*^{-/-}), yet remained viable, fertile, and without marked physiological abnormalities. These models included *Cyp3a*^{-/-}V mice where human CYP3A4 was expressed in high amounts in the duodenum, jejunum, ileum, and colon but not in liver and *Cyp3a*^{-/-}A mice where expression was high in the liver but not in the intestine [71]. *Cyp3a*^{-/-} mice were shown to display a greatly impaired ability to detoxify the cytotoxic drug docetaxel. Expression of transgenic human CYP3A4 in the intestine alone resulted in blockage of parental docetaxel entry from the gut but had very little effect on the systemic clearance of docetaxel. In contrast, liver expression of transgenic CYP3A4 greatly reduced systemic exposure after IV docetaxel administration but had a relatively modest impact on oral administration.

More recently, observations from the same laboratory have shown that CYP2C are upregulated in *Cyp3a*^{-/-} mice and, consequently, contribute to the metabolism of midazolam [72]. Consistent with previous *in vitro* studies [73], their findings showed

that in WT mice, 1'-OH midazolam formation is dependent on not only CYP3A but also CYP2C. Of particular interests were the observations that 1'-OH midazolam formation in Cyp3a^{-/-} mice resulting from CYP2C activity was only slightly lower compared with that in WT mice, and also significant level of 4-OH midazolam formation was seen in Cyp3a^{-/-} mouse liver microsomes, a reaction that was also considered to be CYP3A specific in mice [74]. Midazolam metabolism in small intestinal microsomes from Cyp3a^{-/-} mice was not observed, suggesting that the small intestinal expression of CYP2C enzymes involved in midazolam metabolism is too low to make any significant contribution to the overall clearance. These examples highlight confounding of target metabolism across species, where a probe metabolic pathway in one species may be metabolized by multiple enzymatic pathways in another.

19.4.5.3 CYP3A Chimeric-HL Mouse. A uPA^{+/+}/severe combined immunodeficient transgenic (uPA^{+/+}/SCID) mouse line (see Section 19.3.3) has been established, in which the liver could be replaced by more than 80% with human hepatocytes. Given that the liver is the critical organ involved in the pharmacokinetics of drugs, one could argue that human liver is essential for the development of new drugs. In this regard, to better predict the human drug metabolism and pharmacokinetics, human hepatocytes and liver microsomes are frequently used. Thus, chimeric-HL mice with humanized liver provide an advantage in studies on drug metabolism and pharmacokinetics. Human CYP3A4 mRNA and human CYP3A4 protein can be detected using human albumin as a marker by real-time reverse-transcription polymerase chain reaction (RT-PCR) and western blotting, in a chimeric mouse model [75]. *Ex vivo* studies using hepatocytes from these chimeric-HL mice with near-completely humanized liver were used to investigate the induction of human CYP1A2 and CYP3A4 mRNA by BNF and rifampicin (Rif), respectively. For both P450s, their mRNA was significantly increased compared to fresh human hepatocytes [76]. The same group conducted additional evaluation by evaluating the effects of Rif treatment [intraperitoneal (IP)] on dexamethasone metabolism [77]. The expression levels of human CYP3A4 mRNA and CYP3A4 protein and dexamethasone 6-hydroxylase activity, specific for human CYP3A4, were increased 8- to 22-, 3- to 10-, and 5- to 12-fold, respectively, by treatment with Rif. The authors postulated that because dexamethasone is mainly metabolized to 6-hydroxyldexamethasone in human but to 6-hydroxy-9 α -fluoro-androsta-14-diene-11 β -hydroxy-16 α -methyl-3,17-dione in mice [78], increase in dexamethasone-6-hydroxylase suggested that the human CYP3A4 in the chimeric-HL mice had induction potential. This hypothesis was supported by studies, again from the same group, who investigated CYP3A4 mRNA, protein, and enzyme activity in liver of chimeric-HL mice following exposure to an analogue of Rif, rifabutin which is a specific inducer of human CYP3A4 but not mouse Cyp3a [79]. Each marker was found to be significantly elevated in chimeric mice. In contrast, rifabutin was not shown to increase the murine Cyp3a enzyme activities in the control mice. Together all these studies lend themselves to suggest that, given the environment of P450s in the liver, chimeric-HL mice resembles human *in vivo* more so than they do WT mice, the chimeric-HL mouse line could be a useful animal model to predict CYP3A4 induction in human.

In summary, the previous sections have reviewed the broad applications of chimeric, humanized, as well as KO/knock-in animals for predicting the variation of metabolism by cytochrome P450s, disposition of drugs or drug candidates, *in vivo* drug-drug interactions, and pharmacokinetics and pharmacodynamics for individualized drug therapy

in the human population. The multitude of available models will also permit investigations into the physiological significance of these endogenous substrates. Given the diverse nature of the models available, there is no single model that provides significant advantage over the others. Each will have its advantages and disadvantages, based on the question being asked.

19.5 EPOXIDE HYDROLASES

EHs (formerly epoxide hydratase or epoxide hydrase) were first identified as detoxification enzymes [80]. The two mammalian xenobiotic-metabolizing EHs, microsomal epoxide hydrolase (mEH) and soluble epoxide hydrolase (sEH), are members of the α/β hydrolase fold family of enzymes [81–83]. The α/β hydrolase fold family contains a catalytic triad that consists of a nucleophile for formation of an acyl or an alkyl enzyme intermediate, a general base, and a charge relay residue [84]. This family is diverse, consisting of a broad variety of enzymes, including esterases (i.e., AChE, EHs, haloalkane dehalogenases, and lipases [85].

EH catalyzes the hydrolysis of epoxides (also called *oxiranes*) to corresponding *trans*-dihydrodiols with water as the cofactor. Epoxides are cyclic ethers with three ring atoms, and due to the short bond angle of their ring system, the ring is highly strained. Depending on the substitution pattern of the epoxide, the epoxide may have significant electrophilic reactivity and thus when formed via metabolism may have the potential to be a reactive metabolite. Reactive electrophiles can potentially react with nucleic acids (DNA) and proteins, leading to mutagenic, toxic, and carcinogenic effects [86,87]. However, some epoxides are relatively stable at physiological pHs (i.e., carbamazepine-10,11-epoxide [88,89]), but they still may be associated with toxicity [90,91]. The addition of water to epoxides by EH to form the corresponding *trans*-dihydrodiols is one way in which the body can eliminate epoxides and is usually considered a detoxification pathway. However, in certain circumstances (i.e., benzo[a]pyrene-4,5-oxide), diol formation maybe an intermediate step for the formation of a second epoxide (i.e., via the cytochrome P450 system [92]) and these paired reactions can result in an epoxide with vastly increased mutagenic and carcinogenic properties [86,93,94].

19.5.1 Microsomal Epoxide Hydrolase

mEH is the major xenobiotic-metabolizing EH with a broad substrate selectivity against a diverse group of epoxides [95]. Substrates for mEH are epoxides, hydrophobic in nature, and mono-1,1-di, or 1,2-*cis*-disubstituted. mEH can accommodate bulky substrates such as benzo[a]pyrene-4,5-oxide as well as less bulky compounds such as octane-1,2-oxide. *trans*-1,2-Disubstituted or trisubstituted epoxides are poorly metabolized if at all. However, *trans*-1,2-substituted epoxides are potential substrates of sEH.

mEH has been found in nearly all evaluated mammalian tissues and it is particularly concentrated in the liver, testes, lungs, kidneys, adrenal gland, and intestines. mEH is located in the smooth endoplasmic reticulum; however, there have been a few reports indicating that it is also located on plasma membranes [96,97]. Within the endoplasmic reticulum, mEH is attached to the membrane with a single N-terminal anchor [98] and is facing toward the cell cytosol [99] similar to the CYP enzymes and not toward the endoplasmic reticulum lumen, like the UGTs. A few endogenous substrates have been

reported for mEH, including androstene oxide and estrooxide [100], suggesting a role in development. Recently, mEH has been linked to neurodegenerative disorders such as Alzheimer's and Parkinson's disease [101,102]. Epoxy fatty acids such as epoxysteric acid are relatively poor substrates for mEH compared with sEH (Section 19.5.2).

19.5.1.1 mEH-Null (Knock-Out) Mouse Model. In a study by Miyata *et al.* [103], mEH-null mice were produced to evaluate the physiological importance of mEH and to evaluate the impact of mEH on 7,12-dimethylbenz[a]anthracene (DMBA) carcinogenesis. To produce mEH-null mice, ES cell clones heterozygous for the disrupted *mEH* gene were prepared and injected into C57BL/6 blastocysts to generate germline chimera mice. Pseudopregnant recipient NIH Swiss females were then impregnated with the injected blastocysts to produce germline chimeras mice. The male were bred with C57BL/6 females to establish heterozygous offspring. Homozygotes were then produced from the heterozygous mice that had germline transmission of the targeted mEH allele. The mEH-null mice produced were found to have no obvious phenotype, indicating that mEH is not essential for reproduction and physiological homeostasis. The mice were then subsequently utilized to evaluate DMBA carcinogenesis.

DMBA is a polycyclic hydrocarbon carcinogen that requires multiple metabolic steps to produce the active carcinogenic metabolite. mEH catalysis is required to produce the diol that undergoes subsequent epoxidation by CYP1B1 [92]. Therefore, it would be predicted that mice lacking mEH would be resistant to DMBA-induced cancer. This hypothesis was tested using the mouse skin cancer bioassay with both an initiation-promotion protocol and the complete carcinogenesis protocol. In the initiation-promotion protocol, DMBA was utilized topically for initiation and 12-*O*-tetradecanoylphorbol-13-acetate (TPA) was used during the promotion phase. For the complete carcinogenesis study, only DMBA was applied. In the promotion protocol, about 20% of the mEH-null mice developed papillomas at 17 weeks compared to 70% of the WT controls at 15 weeks. In the full carcinogenesis protocol, after 25 weeks of treatment, nearly 80% of the WT mice had papillomas, whereas there were no evident papillomas on the mEH-null mice. Thus, mEH-null mice were found to be resistant to DMBA-skin cancer. However, the fact that tumors were found in mEH-null mice treated with TPA suggests a second activation pathway for DMBA, which is dependent on TPA. These findings could be further investigated using P450-null mice as well as mEH-null mice.

The impact of mEH on DMBA toxicity was further investigated, where DMBA was administered orally [104]. In this study, the mEH-null mice were bred from mEH-null/- mice [103] obtained from the National Institute of Health. mEH-null/- and control mice were orally gavaged with DMBA (0, 17, 50, and 150 mg/kg) once a day for five days. DMBA treatment of mEH/- mice did not produce changes in body weight, spleen weight, or spleen cellularity, which was observed with the WT mice. In contrast to the WT mice, DMBA treatments did not affect the plaque forming cell response, alter natural killer cell activity, or affect B-cell mitogenesis (although T-cell mitogenesis was partially suppressed at the 50 and 150 mg/kg doses) in mEH/- mice. To determine if the difference observed between the two groups of mice could have been due to differences in pharmacokinetics (drug distribution), the biodistribution of DMBA was determined in the WT and the mEH/- mice in the spleen, thymus, and liver after 24 h and 7 days of oral dosing. The concentrations of DMBA were not significantly different between the WT and the mEH/- mice, demonstrating that mEH is crucial for the activation of DMBA *in vivo*.

KO mice have also been utilized to evaluate benzene toxicity [105,106]. Benzene is another example of toxicity, where mEH is involved in the formation of an intermediate that undergoes subsequent metabolism to the final reactive form. It was interesting to note that in a study by Bauer *et al.* [103], benzene-induced toxicity was observed in the WT male but not in the WT female. As in the previous studies, the mEH^{-/-} mice (male and female) did not exhibit toxicity on the administration of benzene. In the study of Recio *et al.* [106], the additional NAD(P)H: quinone oxidoreductase 1 (NQO1)-null mice were also included in the study design to further elucidate the mechanistic pathways.

mEH^{-/-} mice have also been utilized in studies evaluating the impact of mEH on detoxification pathways [107]. In a study evaluating the impact of mEH^{-/-} mice on the toxicity of 1,3-butadiene (BD) and its metabolite [butadienediepoxy (BDO₂)], the mEH^{-/-} and WT mice were exposed to 20 ppm BD (inhalation) or 30 mg/kg BDO₂ (IP injection). The Hprt mutant frequencies (MFs) were significantly higher in the mEH^{-/-} group exposed to BD when compared to controls (12.4-fold increase) and significantly greater than the corresponding WT group (5.4-fold increase). Additionally, mEH^{-/-} mice exposed to BDO₂ exhibited a significant increase in MF over controls (4.5-fold increase) and WT mice (1.7-fold increase). Genomic damage (measured via comet tail moment) of BDO₂ was evaluated in controls, WT, and mEH^{-/-} mice. mEH^{-/-} mice exposed to the high dose of BDO₂ exhibited significantly more DNA damage than all other groups (2.3- to 27.9-fold increase). Thus, the absence of mEH catalytic activity increases the genetic sensitivity of mice exposed to BD and BDO₂, which is consistent with mEH catalysis being a component of the detoxification pathway.

19.5.1.2 mEH and sEH Chimeric-HL Mouse Model. Nishimura *et al.* [108] investigated the hepatic mRNA expression of human DMEs by TaqMan real-time RT-PCR in chimeric-HL mice with almost completely humanized liver (replacement index (RI): 71–89%). The humanized mice were prepared using the method outlined in Section 19.3.3 using (uPA^{+/+}/SCID) mice. The mRNA of 35 phase I enzymes, including the mRNA of mEH (EPHX1) and sEH (EPHX2) were evaluated. The ratio of the target mRNA levels in the chimeric-HL mice when compared to target mRNA levels in human liver were ~0.75 and 0.6 for mEH and sEH, respectively. Chimeric-HL mice with humanized liver represent another transgenic model for evaluation of mEH and sEH.

19.5.2 Soluble Epoxide Hydrolase

sEH does not have the broad xenobiotic substrate selectivity of mEH; however, it complements mEH in that it is capable of hydrolyzing 1,2-*trans*-substituted epoxides [109]. Typical xenobiotics metabolized by sEH are *trans*-stilbene oxide and *trans*-ethylstyrene oxide. Unlike mEH, sEH does not generally metabolize bulky substrates; however, sEH does metabolize a limited number of PAH epoxides to their corresponding diols [110]. The primary substrates for sEH are endogenous epoxides such as arachidonic epoxides (also called *epoxyeicosatrienoic acids* or EETs), linoleic acid epoxides, and other epoxides derived from fatty acids [111–113]. Owing to its importance in lipid metabolism, sEH has recently been identified as a potential target for multiple therapeutic indications including hypertension [114,115], inflammatory disease [116], diabetes [117], and stroke [118].

sEH has been found in nearly all evaluated mammalian tissues, including liver, lungs, kidney, adrenals, brain, and intestines. sEH was first identified in the cell cytosol [119], which is why it was previously known as *cytosolic epoxide hydrolase*; however, in some cells, sEH has also been identified in peroxisomes [120,121], and therefore, the current naming convention has been updated. sEH catalysis also appears to be involved in a toxicity pathway via its formation of a dihydrodiol from the epoxide of an unsaturated fatty acid. The diol of leukotoxin, the epoxide of linolenic acid, has been implicated as the causative agent of the multiple organ failure and adult respiratory distress syndrome after severe body burns previously associated with leukotoxin [111,122,123]. In mice, where sEH is the major leukotoxin-metabolizing enzyme, pre-treatment with a sEH inhibitor decreases the toxic effects of leukotoxin [111].

19.5.2.1 sEH-Null (Knock-Out) Mouse Model. In studies by Sinal *et al.* [124,125], sEH-null mice were produced to evaluate the impact of sEH on blood pressure and renal arachidonic acid (AA) metabolism. To prepare the sEH^{-/-} mice, a fragment containing exon 1 was isolated from mouse sEH genomic clones and subcloned into pUC9. Bacterial phosphoribosyltransferase II gene cassette (TK-Neo) was used to disrupt the gene. ES cell clones prepared using the disrupted *sEH* gene were injected into blastocysts (Genome Systems). The subsequent male chimeric mice were crossed with C57BL6 females to obtain heterozygous mice. The heterozygous mice were then crossed to produce WT, heterozygous mice, and the sEH^{-/-} mice. Systolic blood pressure was then monitored in the mice in both the presence and absence of salt loading. The systolic blood pressure in sEH^{-/-} male mice was significantly lower than the blood pressure in the WT male mice in both the absence and presence of the dietary salt loading. Female mice (WT and sEH 9^{-/-}) had blood pressures significantly lower than the WT male mice.

For *in vitro* evaluation of the impact of sEH^{-/-} mice on AA metabolism, S9 fractions were prepared from the liver and the kidney of WT and sEH^{-/-} mice. AA is metabolized via CYP450s to EETs and then subsequently metabolized to dihydroxyeicosatrienoic acids (DHETs) by sEH. In the liver S9 fractions from WT mice, the level of EETs was extremely small in contrast to the sEH^{-/-} mice. However, the corresponding levels of DHETs were much higher in the WT mice as compared to the sEH^{-/-} mice. It was hypothesized that the small level of DHETs observed in the liver fractions of the sEH^{-/-} mice could be due to mEH metabolism as mEH metabolizes EETs albeit much less efficiently than sEH. The kidney S9 *in vitro* data were consistent with the liver data in that the levels of DHETs observed was greatly reduced in the sEH^{-/-} mice. Striking sex differences were observed in the formation of DHETs from EETs in the kidney fractions with AA metabolites much greater in males than females. The *in vitro* findings were consistent with the *in vivo* findings of the sex differences observed for the impact of sEH^{-/-} mice. These data provide evidence for the role of sEH in blood pressure regulation and thus, sEH as a target that could be used to regulate blood pressure associated with hypertension.

In addition to the examples above, the impact of sEH on EET metabolism has also be evaluated in brain [126,127]. To test the hypothesis that *sEH* gene deletion would be protective against focal cerebral ischemia [126], sEH^{-/-} mice with and without an EET antagonist (14,15-epoxyeicosa-5(Z)-enoic acid) were subjected to a 2-h middle cerebral artery occlusion and the subsequent infarct size was measured and compared to WT controls. sEH detected via immunohistochemistry was detected in WT but not

sEH^{-/-} mice brains. The EET metabolite DHET was abundantly present in the WT mice but virtually absent in the sEH^{-/-} mice, which is consistent with the sEH-null phenotype. However, the levels of EETs in brain tissue between WT and sEH^{-/-} mice were not significant thus suggesting an alternative route of elimination of EETs in mouse brain. The infarct size was significantly smaller with regional cerebral blood flow rates significantly higher in sEH^{-/-} mice when compared to WT mice. It was interesting to note that the presence of the EET antagonist did not alter infarct size.

In a follow-up study [127], sex differences in EET metabolism and infarct size were evaluated in sEH^{-/-} mice. In WT female mice, sEH activity was lower, DHET levels were lower, cerebral blood flow was higher, and infarct size post middle cerebral artery occlusion was lower than in male WT mice. These sex differences were not observed in sEH^{-/-} mice and were negated in female WT mice following ovariectomy. This is consistent with the impact of estrogen on sEH. Thus, it was concluded that sEH activity was an important mechanism underlying sex-linked differences in blood flow and brain damage after cerebral ischemia in mice.

sEH^{-/-} mice are a key tool in evaluating the physiological impact of sEH on disease states and subsequently building evidence of sEH as a potential target for therapeutic intervention. Additional studies have been conducted using sEH^{-/-} mice in regard to blood homeostasis [128], inflammation [128,129], and cholesterol levels [130]. sEH^{-/-} mice have also been utilized to better understand the metabolic formation of toxic metabolites [131]. sEH^{-/-} mice, CYP2E1^{-/-} mice, and *in vitro* studies were used to gain a better understanding of the formation of cyanide from either methacrylonitrile or acrylonitrile, including additional enzyme contributions and understanding the observed sex differences in mice.

19.5.2.2 sEH Humanized (Knock-In) Mouse Model. To evaluate the impact of neuronal overexpression of sEH, Syn1-FLAG-sEH transgenic mice were generated by fusing the rat synapsin 1 promoter to an N-terminally FLAG-tagged cDNA for mouse sEH [132]. The fusion tag consisting of 8 amino acids (FLAG) epitope tag was used to differentiate between endogenous sEH and transgenic sEH. Four transgenic founders were established and two of the founders were successfully bred to create the transgenic lines. Western blots using antibodies against sEH and the FLAG epitope tag showed that the transgenic sEH was limited to the brains and testes of the transgenic mice. A total sEH western blot showed that the overall sEH total brain content was fivefold than that observed in the WT mice (nontransgenic littermates). This corresponded to a threefold increase in sEH activity in the transgenic brain homogenates, which demonstrated that the overexpressed protein was functional.

19.5.2.3 sEH Chimeric-HL Mouse Model. See Section 19.5.1.2 for details.

19.6 OXIDASES

19.6.1 Aldehyde Oxidase

Aldehyde oxidases (AOXs) are molybdoflavoenzymes related to xanthine oxidoreductase (XOR). Rodents have four AOX genes, *Aox1*, *Aoh1*, *Aoh2*, and *Aoh3*, which are located a short distance from each other on chromosome 1c1 in mice and chromosome

9 in rats [133]. Humans have a single functional gene, *AOX1*, and two inactive pseudogenes located on chromosome 2q [133,134]. AOX activity was highest in the livers of all mammals studied, but other organs such as lung, kidney, and small intestine also had activity [135–137]. However, in brain homogenates of preclinical species, AOX activity was very low or absent [138]. The AOX enzymes perform a broad range of metabolic reactions, oxidizing both aliphatic and aromatic aldehydes to their corresponding acids, as well as oxidizing nitrogen-containing heterocycles. A number of species and strain differences have been observed with respect to the AOX activities on a variety of substrates. Some substrates, such as famciclovir and quinoxaline, show metabolic differences between species, while others, such as methotrexate (MTX) and phthalazine, have similar profiles between species. These facts complicate the use of preclinical species for the prediction of human metabolism by AOX.

19.6.1.1 Aldehyde Oxidase Chimeric-HL Mice. To date, the only KO mouse model to be produced is a mouse deficient in *Aoh2*, an enzyme similar to human AOX, but not contained in the human genome [134]. However, the chimeric-HL mouse model reported by Tateno *et al.* [7] (Section 19.3.3), in which mouse livers were repopulated to a high degree with human hepatocytes, has been used in the study of the AOX-catalyzed metabolism of *N*¹-methylnicotinamide (NMN) [139]. In this study, NMN was chosen as a test substrate because of differences observed in the metabolic profiles of humans and normal mice. Nicotinamide is converted to NMN by nicotinamide *N*-methyl transferase, and the subsequent metabolism to *N*¹-methyl-2-pyridone-5-carboxamide (2-PY) and *N*¹-methyl-4-pyridone-3-carboxamide (4-PY) is catalyzed by AOX. The metabolism of NMN is species dependent, with humans forming primarily 2-PY, and mice forming 2-PY and 4-PY in equal abundance [140]. The *in vivo* metabolism of NMN was monitored by measuring NMN, 2-PY, and 4-PY ratios (the RP value) [141] in the urine of chimeric-HL and control mice. The RP value in urine increased as the human hepatocyte RI of the chimeric-HL mice increased. Also, in chimeric-HL mice, the ratio of urinary 2-PY/4-PY increased as RI increased, while in control mice, the amounts of each metabolite were approximately the same. A similar result was also observed *in vitro* by measuring the NMN oxidase activity of liver cytosols produced from chimeric-HL mice, with the 2-PY/4-PY ratio tracking well with the RI. At 80–90% RI, the 2-PY/4-PY ratio in chimeric-HL mice was similar to that observed in pooled human liver cytosol. These results suggest that chimeric-HL mice could be a useful model for AOX-mediated drug metabolism, although the source of the human hepatocytes used for repopulation should be considered due to interindividual variations in human AOX activity [142–144].

19.6.2 Monoamine Oxidases

Amine-containing compounds are ubiquitous in nature, being commonly found in foods and beverages (tryptamine and trimethylamine) [145]; as environmental contaminants (allylamine); in drugs such as sumatriptan and citalopram; in addition to endogenous amines such as the neurotransmitters dopamine (DA), norepinephrine (NE), and serotonin (5-HT). The detoxification and regulation of amines, regardless of source, is critical to maintain normal biological function. In addition to metabolism by cytochrome P450s, amine-containing compounds can also be metabolized by the MAO enzymes. For those compounds that are substrates of MAO, the contribution of these

enzymes to metabolism and clearance can be significant. For example, MAO oxidation represents the primary clearance pathway for some members of the triptan class of antimigraine drugs, such as sumatriptan and rizatriptan. Additionally, *N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is metabolized primarily by MAO-B to the neurotoxic 1-methyl-4-phenylpyridinium (MPP⁺) species, which destroys nigrostriatal dopaminergic neurons [162–164].

MAO is a flavoenzyme found on the mouse X chromosome [149–151]. In humans, it exists in two forms, MAO-A and MAO-B, comprising 527 and 520 amino acids, respectively, with 70% sequence identity [152]. MAO-A and MAO-B have similar X-ray crystal structures [153,154] but different substrate specificities and kinetic properties. For example, MAO-A has a preference for the substrates NE and 5-HT, and is inhibited by low concentrations of clorgyline, while MAO-B is more selective for β -phenylethylamine (PEA) and can be selectively inhibited by low doses of *l*-deprenyl [155].

Deficiencies in either MAO-A or -B have been linked to several different behavioral and developmental abnormalities in animals and humans. Reduced expression of MAO-A can cause mental retardation and increased aggression, as observed in the males of a Dutch family having a mutation in the *MAO-A* gene [156]. Norrie's disease, with symptoms including impaired hearing and blindness, has been linked to genetic defects in the *MAO-B* gene [157,158]. KO models for MAO-A, MAO-B, and MAO-A/B have all been described in the literature, and numerous studies investigating the behavioral characteristics of genetically altered MAO expression in mice have been reported.

19.6.2.1 MAO-A (Knock-Out) Mouse Models. A line of MAO-A KO mice were inadvertently generated by the insertion of a β -interferon (IFN- β) transgene into the gene encoding MAO-A [159,160] in one-cell C3H/HeJ mouse embryos, producing a Tg(H2-IFN- β)8 (Tg8) transgenic line. Abnormal behaviors, including fearfulness, trembling, aggression, and postural changes, were observed in these mice, and the abnormal behaviors varied with age. Pup brain concentrations of 5-HT increased up to ninefold, while those of NE increased twofold in pup and adult brains. MAO-A activity was found to have been abolished via use of 5-HT as a substrate, but no difference was observed in the activity of MAO-B on PEA. Furthermore, chronic administration of parachlorophenylalanine, a 5-HT synthesis inhibitor, reversed the abnormal behavioral traits of the Tg8 pups, but no change was observed with administration of the catecholamine synthesis inhibitor α -methylparatyrosine.

19.6.2.2 MAO-B (Knock-Out) Models. MAO-B KO mice were produced by insertion of a neomycin resistance gene into exon 6. This generated a stop codon in the *MAO-B* gene, resulting in a truncated and inactive enzyme [161]. Injection of selected ES cells into mouse blastocytes derived from male 129/Sv animals resulted in chimeric animals lacking the WT MAO-B allele. Germline transmission was demonstrated by PCR in 90% of the progeny. The effects of MAO-B deficiency did not yield any statistical difference in brain concentrations of the neurotransmitters 5-HT and its metabolite 5-hydroxyindoleacetic acid (5-HIAA), homovanillic acid, DA, 3,4-dihydroxyphenylacetic acid (DOPAC), 3-methoxytyramine, NE, or 3-methoxy-4-hydroxy-phenylglycol between WT and MAO-B-deficient mice. However, urinary and brain concentrations of PEA were approximately eightfold higher in the latter mice. It has been shown previously that the cyclic tertiary amine MPTP is converted to the toxic

metabolite MPP⁺ by MAO-B [162–164], leading to destruction of dopaminergic neurons in the midbrain with symptoms similar to Parkinson's disease. In WT mice, MPTP toxicity produced the depletion of DA and DOPAC, while MAO-B-deficient mice in this study did not suffer similar effects. These observations suggest that this line of MAO-B KO mice may have utility in drug metabolism studies of MAO substrates.

19.6.2.3 MAO-A/B (Double Knock-Out) Models. MAO-A/B double KO mice were produced by a spontaneous point mutation in a colony of MAO-B KO mice [165]. The mutation in exon 8 (A863T) introduced a premature stop codon in the gene for MAO-A in the progenitor mouse, which was propagated by selective breeding. The resulting MAO-A/B double KO mice exhibited a phenotype nontypical of the MAO-B single KO mice, including low body weight and exaggerated starting reactions to normal stimuli. Brain concentrations of 5-HT, NE, DA, and PEA were increased, and 5-HIAA decreased, relative to either MAO-A or MAO-B single KO mice. In a battery of behavioral tests, the characteristics of these mice were also different from those of either MAO-A or MAO-B single KO mice. These differences were principally in the lack of exploratory activity in an unfamiliar open field and in postural attitudes suggestive of fear or anxiety not typical of either MAO-A or B mice. These mice provide an additional tool for the evaluation of drugs for which MAO-A/B metabolism may be important.

19.6.3 Alcohol and Aldehyde Dehydrogenases

Alcohols, most notably ethanol, are metabolized to the corresponding aldehydes by the enzymes alcohol dehydrogenase (ADH), in addition to metabolism by other enzymatic processes. ADH is a family of cytosolic zinc-containing enzymes. These enzymes are dimeric, and each subunit is ~40 kDa. Humans possess five forms of ADH, while mice have only three forms, corresponding to human ADH1, ADH3, and ADH4 [166]. ADH1 and ADH4 both have retinol and ethanol dehydrogenase activity [167–171], while ADH3 is primarily involved in the oxidation of *S*-hydroxymethylglutathione, a product of the reaction of formaldehyde with GSH [147,148].

The aldehydes resulting from ADH oxidation are potentially toxic, and further oxidation to the corresponding carboxylic acids facilitates their detoxification and clearance from the body. The enzymes primarily responsible for this oxidation are the aldehyde dehydrogenase (ALDH), a set of polymorphic enzymes expressed in numerous tissues in the body. The most important of these polymorphs for ethanol metabolism are cytosolic ALDH1 and mitochondrial ALDH2, based on their broad tissue distribution and low K_m values for acetaldehyde of 30 and 1 μM , respectively [146]. Both are tetrameric enzymes, composed of 54-kDa subunits. The precise role of most of the ALDH polymorphs in ethanol metabolism is unknown, but a mutation in ALDH2 in which glutamate is replaced with lysine at position 487, denoted *ALDH2**2 [172,173], has been associated with far higher acetaldehyde levels after consumption of ethanol than in individuals having the normal *ALDH2**1 allele. A large proportion of Japanese, Chinese, and Koreans lack ALDH2 activity due to this mutation, and consumption of alcohol in this population leads to a facial flushing reaction [174,175], which is associated with up to a 10-fold increase in acetaldehyde levels in comparison to individuals who do not exhibit facial flushing [176–178]. An overview of the roles

of ADH and ALDH in ethanol-related pathology has been reported by Crabb *et al.* [179].

19.6.3.1 ADH (Knock-Out) Models. A strain of deer mice (*Peromyscus maniculatus*) naturally deficient in ADH [180] has been used to study various aspects of ethanol metabolism [181,182]. In animals fed a 4% ethanol diet for 60 days, these studies demonstrated increased nonoxidative metabolism of ethanol to fatty acid ethyl esters in ADH^{-/-} versus WT animals, in addition to increased mortality and histological changes to the liver and pancreas.

Other scientists have described a gene KO model in which gene-targeting vectors for murine Adh1, Adh3, and Adh4 were separately introduced into ES cells [183]. Hetero- and homozygous offspring of mice with each mutation developed normally compared with WT mice. Six hours after administration of 3.5 g ethanol/kg body weight, an intoxicating dose, Adh1^{-/-} mice had blood ethanol concentrations of 0.30%, while Adh4^{-/-} mice had concentrations of 0.15%. WT and Adh3^{-/-} mice had blood ethanol concentrations of ~0.03%. Thus, Adh3 was not important for ethanol clearance, while Adh1 and Adh4 played a key role, with the former being more significant. The role of Adh3 in formaldehyde detoxification in these mice was then examined by IP injections of 10% formalin in saline at doses of 0.09–0.22 g/kg. Adh3^{-/-} mice had a formaldehyde LD₅₀ of 0.135 g/kg, where the lethal dose was defined as an amount of formaldehyde resulting in death within 90 min, whereas in WT mice, the LD₅₀ was 0.200 g/kg, a statistically significant difference. For Adh1^{-/-} and Adh4^{-/-} mice, the LD₅₀ values were 0.175 and 0.190 g/kg, respectively, not statistically different from WT mice, suggesting an important role for Adh3 in the clearance of formaldehyde. Mice of each genotype were then administered 100 µg/kg retinol or vehicle control, then retinoic acid (RA) levels were measured after 2 h in kidney homogenates. Vehicle-treated mice had undetectable levels of RA in kidney tissue, while retinol-treated WT, Adh1^{-/-}, and Adh4^{-/-} mice had RA levels of 273 ± 186, 57 ± 15, and 34 ± 16 pmol/g, respectively. Thus, Adh1 and Adh4 played an important role in the ability to metabolize retinol to RA. A second study in this line of Adh1, Adh3, and Adh4 KO mice was used to examine retinol metabolism in more detail [184]. In this study, liver concentrations of RA were measured 2 h after administration of 50 mg/kg all-*trans*-retinol. WT mice produced 2.0 mg/g RA, Adh1^{-/-} mice had a 10-fold reduction in RA, Adh3^{-/-} mice had a 3.8-fold reduction, and Adh4^{-/-} mice had an insignificant reduction in RA levels. These results suggest that Adh1 is mainly responsible for retinol metabolism, with a lesser role for Adh3.

19.6.3.2 ALDH KO Models. A line of Aldh2^{-/-} KO mice was produced by gene-targeting techniques in ES cells [185]. Male chimeras were mated with female C57BL/6 mice. Liver subcellular fractions were generated from these mice to investigate the ability to oxidize methoxyacetaldehyde (MALD) to methoxyacetic acid (MAA). No oxidation was observed in mitochondrial fractions, and very low activity was observed in cytosolic fractions as compared with activities using fractions derived from Aldh2WT mice, suggesting that ALDH2 is the key enzyme involved in the oxidation of MALD. This strain of mice has also been used to investigate the inhalation toxicity of acetaldehyde [186] with the conclusion that toxicity is greater in Aldh2^{-/-} mice and therefore that toxicity may also be greater in humans with low ALDH2 activity. A pathological study of acetaldehyde toxicity has also been

performed using this model [187]. Other investigators have used this strain to study the effects of subacute ethanol treatment on the survival rate and expression of Aldh1, Aldh2, Cyp1a1, Cyp2e1, and Cyp4b1 enzymes [187]. The authors conclude that mortality is higher in the Aldh2^{-/-} mice after ethanol treatment and that Cyp2e1 is inducible in this model after treatment as compared to Aldh2WT mice. Other application of the Aldh2^{-/-} mouse model include (i) the effect of ethanol on DNA and Cyp2e1 expression in liver using this strain [188] and (ii) formation of DNA adducts of *N*2-ethylidene-2'-deoxyguanosine as a product of ethanol exposure [189].

19.6.4 Flavin Monooxygenases

The FMO enzymes are a family of enzymes located in the endoplasmic reticulum, which catalyze the oxidation of nucleophilic heteroatoms such as nitrogen, sulfur, and phosphorus. Their substrate specificity overlaps with other DMEs, such as cytochrome P450s. There are five distinct *FMO* genes and six pseudogenes in humans [190–192], while mice have nine genes [191]. One or more FMO isoforms are expressed in almost all the various mammalian tissues examined. FMOs 1–5 have a primary amino acid sequence which is >50% identical, and the corresponding FMOs across species are more than 80% identical [193]. FMO1, FMO2, and FMO3 are the predominant xenobiotic-metabolizing enzymes among all the species studied. The level of expression of these isoforms is dependent on species, tissue, sex, and stage of development. In adult humans, FMO3 is the most abundant isoform found in liver, along with lesser amounts of FMO5, while in the lung of humans and most other species, FMO2 is dominant. Male rat liver contains abundant amounts of Fmo1, which is absent in adult human liver [194]. Sex differences have been observed in mice, with females producing Fmo1 and Fmo3 in equal amounts, whereas males did not express Fmo3, and Fmo1 was found at less than half the amounts in females. Fmo5 expression was low but equal in male and female mice [195,196].

19.6.4.1 FMO (Knock-Out) Mouse Model. Despite these differences from human FMO expression, a mouse FMO KO model has been reported to investigate the role of this enzyme in drug metabolism. The model was produced by Cre-loxP-mediated deletions of the mouse *Fmo1* gene and portions of the *Fmo2* and *Fmo4* genes [197,198]. It was used to investigate the contribution of FMO1 to interindividual variations in plasma concentrations (greater than 30-fold) [199,200] observed in patients taking the antidepressant drug imipramine. Imipramine is converted to an active metabolite, desipramine, by CYPs 1A2 and 3A4 [201] and is inactivated by hydroxylation via CYP2D6 [202] and N-oxygenation via FMO1 [203,204]. Following a 30 mg/kg IP injection of imipramine, WT mice appeared sedated and had impaired motor coordination within 15 min. The KO mice developed body tremors and spasm within 25 min, unlike the WT mice, suggesting differences in metabolism of the drug. The serum concentrations of imipramine at 20 min postdose were 2.7-fold higher in KO mice than in WT mice ($p < 0.001$). Imipramine-*N*-oxide was present in tissues of WT mice, but were absent in the KO mice, further demonstrating metabolic differences in this model.

19.7 ESTERASES

19.7.1 Cholinesterases

Cholinesterases comprise two sets of enzymes that hydrolyze esters of the neurotransmitter choline. AChE is selective for acetylcholine hydrolysis and functions to terminate nerve impulse conduction in the nerve synapse. BChE, also known as *pseudocholinesterase* or *nonspecific cholinesterase*, is active on a variety of ester substrates, such as succinylcholine and heroin [205], in addition to acetylcholine. AChE and BChE each have nonesterase activity as well, including hydrolysis of substance P [206,207], and the hydrolysis of enkephalins by AChE [208]. The two cholinesterases share ~50% sequence identity [209] and are found in numerous tissues, including muscle, nerve, blood, and heart [210]. In human and mouse brains, AChE activity predominates, in muscle, AChE and BChE activities are similar, but in plasma and other tissues of the body, BChE activity is greater than that of AChE [210,211].

Disruptions in either brain AChE activity or the levels of acetylcholine are observed in neurologic diseases such as Alzheimer's disease (AD) [212–218]. Additionally, acute exposure to organophosphate compounds, such as parathion or the nerve gas sarin, and carbamates such as the pesticide carbaryl, inhibit AChE and can produce seizures and death by respiratory arrest due to the overstimulation of cholinergic neurons [219,220]. Also, naturally occurring BChE deficiencies have been observed in the human population [221,222], contributing to phenomena such as prolonged apnea in patients receiving the muscle relaxant succinylcholine [223–225]. Inhibition of BChE by the bronchodilator bambuterol has been shown to decrease the clearance of another muscle relaxant, mivacurium, prolonging the duration of neuromuscular blockade by three- to fourfold [226]. In all the foregoing examples, AChE and/or BChE KO mice can be used as tools to further investigate the metabolism of compounds known to be substrates or inhibitors of these enzymes.

19.7.1.1 Acetylcholinesterase (Knock-Out) Mice. An AChE KO mouse (AChE^{-/-}) model was produced by gene-targeting techniques in which a targeting vector was introduced into R1 ES cells [227]. Five kilobase of the mouse *AChE* gene on exons 2–5 was deleted by this procedure, removing 93% of the amino acids comprising this gene. Mice produced from cell colonies having the desired gene deletion were mated with 129sv mice to produce offspring having the desired AChE KO. A previous study in *Drosophila* [228] in which AChE was deleted by targeted mutagenesis resulted in the death of the embryos. In the mouse KO, however, the pups survived on average 14 days after birth. In later studies, the average lifespan of the AChE KO mice could be extended to 60–80 days by feeding the dams a high fat diet during the nursing period, and feeding the pups a liquid high fiber diet after weaning. The surviving pups were smaller than their heterozygous AChE^{+/-} or WT littermates and had other phenotypic abnormalities such as lack of a righting response, sealed eyelids, and the development of a fine motor tremor three to four days after birth. The postnatal survival of these mice was proposed to be due to the action of intact BChE on acetylcholine [229], which could possibly compensate for the absence of AChE. Toxicity studies [227] with the nonselective esterase inhibitor diisopropylfluorophosphate (DFP) and the BChE-specific inhibitor

bambuterol demonstrated an increased sensitivity of these KO mice to DFP. A dose of DFP which was sublethal to WT mice killed AChE^{-/-} mice within 3 min and had an intermediate level of toxicity to AChE^{+/-} animals. The administration of bambuterol at 0.3 mg/kg had no effect on WT mice but killed AChE^{-/-} animals within 10 min.

The AChE^{-/-} mouse model was used to investigate the toxicity of the nerve agent *O*-ethyl-*S*-[2-(diisopropylamino)ethyl]methylphosphonothioate (VX) relative to WT mice [230]. VX is the most potent organophosphorus ester known and inhibits both AChE and BChE. It is poorly reactive with carboxylesterase, however, which in rodents is in great excess over the cholinesterases. The AChE^{-/-} mice were observed to be more sensitive to VX than WT mice, with an LD₅₀ of 10–12 µg/kg, approximately one half that of normal mice. These and other observations by the authors led to the conclusion that VX toxicity is due at least in part to the inhibition of targets other than AChE.

In severe AD, AChE activity is greatly reduced, while BChE activity in the brain may remain unchanged or even increase [216,231,232]. One proposed therapeutic approach in AD treatment is to use BChE inhibitors in an effort to increase brain ACh levels. Naik *et al.* [232] have used these AChE KO mice to investigate the effect of the AChE-inhibiting drugs rivastigmine and donepezil on extracellular concentrations of ACh in the hippocampus of AChE^{-/-} mice. ACh levels were 30-fold higher in AChE^{-/-} mice than in WT mice before drug administration. After administration through a microdialysis probe of 1 µM rivastigmine, an inhibitor of both AChE and BChE, ACh levels increased a further twofold within 90–120 min. In contrast, administration of 1 µM donepezil, a selective inhibitor of AChE, did not produce any further increase in hippocampal ACh levels in AChE^{-/-} mice, although in WT mice, it increased ACh levels more than twofold. The authors concluded that inhibition of BChE by rivastigmine led to a significant increase in ACh levels and may be an important observation relevant to the treatment of AD.

19.7.1.2 Butyrylcholinesterase (Knock-Out) Mouse Model. BChE KO mice were produced by gene-targeting techniques in which 891 bp were deleted from the *BCHE* gene [233]. Propagation of the line was effected by breeding BChE^{+/-} mice to produce BChE^{+/+}, ^{+/-}, and ^{-/-} littermates. BChE^{-/-} mice have no differences in appearance, weight gain, reflexes, or fertility relative to WT mice [234]. In this regard, these mice are proposed as a model for human BChE deficiency, since humans with “silent” BChE, caused by various mutations in the *BCHE* gene, appear normal until challenged with a BChE substrate, such as succinylcholine [235–237]. Tolerant to the AChE-specific inhibitors donepezil and (–)-huperzine A was investigated in both AChE-deficient and BChE-deficient mice [230]. A dose of donepezil, which was non-lethal to WT mice, was toxic to BChE^{+/-} and ^{-/-} mice, with the greatest toxicity evident for the ^{-/-} mice. AChE^{-/-} mice, however, did not exhibit any toxic symptoms. Following a nonlethal dose of (–)-huperzine A to WT, ^{+/-}, and ^{-/-} mice, similar results were observed, with toxic symptoms increasing for BChE^{+/-} and ^{-/-} mice, and, as with donepezil, AChE^{-/-} mice did not exhibit any toxicity. These results indicated a role for BChE in the hydrolysis of acetylcholine *in vivo*.

BChE^{-/-} mice were used to investigate the toxicity of cocaine in the absence of this esterase [238]. In mice, cocaine is inactivated by BChE and carboxylesterase, while humans detoxify 90% of the drug via BChE [239]. Human toxicity of cocaine is not well correlated to dose or blood concentrations, and it has been suggested

that low BChE levels due to natural genetic variations may be involved [240]. In this study, cocaine or saline vehicle was administered to BChE $+/+$, $+/-$, and $-/-$ mice at 20 mg/kg for seven days before sacrifice. Liver morphology was then assessed microscopically. Changes were observed to the greatest extent in BChE $-/-$ mice, which displayed lymphocytic infiltration, hepatocellular dropout, and regeneration. Progressively less pathology was observed in the livers of BChE $+/-$ and $+/+$ mice, respectively. No differences in cardiac function were observed between BChE $+/+$ and $-/-$ mice coadministered a single 100 mg/kg dose of cocaine and 2 mg/kg CBDP, a carboxylesterase inhibitor. However, respiration rates were decreased significantly in BChE $-/-$ mice, and remained lower through 12 h postdose, while respiratory rates in WT mice returned to normal after 30 min. All BChE $-/-$ mice also exhibited apneusis (termination of breathing at end-inspiration), while none of the BChE $+/+$ mice presented this symptom. The authors therefore concluded that the observed hepatotoxicity of cocaine and the respiratory effects were due to the absence of BChE in the deficient mice and suggest that natural mutations in BChE may potentiate the effects of cocaine and possibly other drugs, in human beings. The authors suggest the use of this model for the determination of other drug sensitivities in patients with BChE deficiencies.

19.8 UDP-GLUCURONYL TRANSFERASE

UGTs are a family of enzymes that catalyze the glucuronidation of endogenous compounds and xenobiotics utilizing the cofactor UDP-glucuronic acid (UDPGA). UGTs are separated into two major subfamilies based on amino acid sequence similarities [241–243]. Members within a single UGT subfamily exhibit greater than 60% sequence similarity. The differences in the UGT1 family are confined to the N-terminus, with all members of this family having an identical 246 amino acid carboxy terminus. In contrast, the differences in the UGT2 family are observed throughout the protein [241–243].

UGTs are membrane-bound enzymes located in the endoplasmic reticulum [244]. They are found primarily in the liver and are also present in other tissues, including intestine, kidney, skin, lung, and brain [245–247]. UGTs catalyze the formation of a wide variety of glucuronide conjugates, including oxygen, nitrogen, sulfur, and even carbon glucuronides [245]. Glucuronide conjugates are primarily excreted in the urine. However, biliary excretion may become an important route of elimination when the molecular weight of the glucuronide conjugate exceeds 300 Da [248]. Glucuronide conjugates excreted in the bile may be hydrolyzed to their unconjugated forms via β -glucuronidase enzymes present in the intestines. These unconjugated products may subsequently be reabsorbed in the intestines, thus undergoing enterohepatic recirculations [249]. Glucuronidation catalyzed by the UGTs is a major pathway for drug metabolism and elimination in humans. The human UGT enzymes most commonly listed in catalyzing drug glucuronidation are UGT1A1, UGT1A4, and UGT2B7 [250].

19.8.1 UGT1A (Knock-Out) Mouse Model

Genetic polymorphism of some UGT isoforms have been reported, most notably for UGT1A1. Many mutated alleles of UGT1A1 have been identified and some mutations

leading to decreases in UGT1A1 enzymatic activity have been associated with Crigler-Najjar syndrome and Gilbert's syndrome in humans [246]. Crigler-Najjar syndrome and Gilbert's syndrome are the result of unconjugated bilirubin. Crigler-Najjar syndrome type 1 is diagnosed as a complete lack of bilirubin glucuronidation and is often fatal.

In a study by Nguyen *et al.* [251], the physiological importance of the Ugt1 locus in mice was evaluated via the creation of Ugt1 KO (Ugt1^{-/-}) mice. Ugt1^{-/-} mice were developed via an interruption to exon 4 in the Ugt1 locus in C57BL/6 mouse blastocysts. Male chimeras were then backcrossed into C57BL/6 females to generate heterozygous founders that were bred to develop Ugt1^{-/-} mice. In mouse liver, Ugt1a1, Ugt1a5, Ugt1a6, and Ugt1a9 are the predominant forms of Ugt1a [247]. There were no detectable levels of UGT1A RNA or UGT1A proteins in liver microsomes from Ugt1^{-/-} mice. However, cross-reactive UGT2 proteins were detected via immunoblot in the Ugt1^{-/-}, Ugt1^{+/-} heterozygous, and WT mouse livers using a human anti-2B7 antibody. UGT1A enzymatic activity in Ugt1^{-/-} mouse liver microsomes was evaluated using the probe substrates bilirubin and thyroxine. Neither bilirubin nor thyroxine conjugation was observed in Ugt^{-/-} mice microsomes. The thyroxine activity in Ugt^{+/-} mice was 50% that of WT mice in microsomes. In contrast, testosterone metabolism (which was utilized as a UGT2B probe substrate based on activity data in monkey [252] and humans [253]) was similar for the Ugt1^{-/-}, Ugt^{+/-}, and WT mice. These findings suggest the interruption to exon 4 in the Ugt1 locus affected UGT1A but did not affect the formation or enzymatic activity of UGT2B *in vivo*, the newborn Ugt1^{-/-} mice developed serum levels of unconjugated bilirubin that were 40–60 times higher than Ugt 1^{+/-} heterozygous mice or WT mice, respectively. The highly elevated levels of unconjugated bilirubin observed in the Ugt1^{-/-} mice were consistent with the values observed in humans with Crigler-Najjar type 1 syndrome. Extreme diagnostic jaundice due to elevated bilirubin levels was observed in the skin of Ugt1^{-/-} mice within 8 h. However, at five days old, thyroxine levels in the neonates were similar between Ugt^{-/-} and Ugt^{+/-}, indicating more complex mechanisms *in vivo* than simply UGT1A activity for thyroid hormones. Overall, the interruption of the Ugt1 locus was a lethal mutation with all Ugt1^{-/-} mice dying within two weeks of birth.

19.8.2 UGT1A Humanized (Knock-In) Mouse Model

To establish the transgenic UGT1 knock-in mice (Tg-UGT1 mice) [254], a purified BAC encoding the entire human UGT1 locus was microinjected into the pronucleus of CB6F₁ (a F1 hybrid between BALB/c and C57BL/6 N mice) mouse eggs and transplanted into pseudopregnant C57BL/6 N mice. The subsequent offspring were genotyped and five founders containing the entire UGT1 locus were bred into C57BL/6 N mice. The insertion of the DNA did not affect fertility and there were no gross pathological differences from the WT littermates. It should be noted that the addition of the human UGT1 was on a background of mouse UGTs.

Microsomes were prepared from the liver and large and small intestines of the Tg-UGT1 mice. Using antibodies for specific human UGTs, UGT1A1, UGT1A4, and UGT1A6, expression levels were determined for the Tg-UGT1 mice and compared to both human liver microsomes and expressed UGTs prepared from SF-9 insect cells. UGT1A1 was found to be expressed in both the small and large intestines (being more abundant in the small intestines). UGT1A4 was also observed in the small intestines at similar levels to UGT1A1. In contrast to UGT1A1 and UGT1A4, UGT1A6 was

difficult to detect in the small intestines but was observed in the colon. In the liver, there was limited expression of UGT1A1 and UGT1A4 but UGT1A6 was observed at levels similar to human microsomes. There were, however, differences in expression levels across the Tg-UGT1 mice examined. *UGT1A* gene expression was also evaluated across multiple tissues (liver, brain, stomach, small intestines, colon, kidney, and heart). UGT1A10 was found to be exclusively expressed in nonhepatic tissues. UGT1A6 and UGT1A9 were the predominant forms identified in the kidney. Induction patterns were evaluated in the Tg-UGT1 mice (in comparison to the WT mice) with activity evaluated using probe substrates. UGT induction by pregnenolone-16 α -carbonitrile (PCN) and TCDD was observed in the Tg-UGT1 mice and appeared to be dependent on glucocorticoids.

The expression levels of human UGT1 isozymes and the induction profiles suggest that this model will be useful to examine the functional and regulatory properties of human UGT1. This model has subsequently been utilized to understand the impact of a peroxisome-proliferator-activated receptor (PPAR) agonist [255,256], an Ah receptor agonist (chrysin) [257], liver-X-receptor (LXR α) agonists [258], and Nrf2-Keap-dependent UGT1A1 induction by prooxidants [259] in Tg-UGT1 mice. A UGT1A knock-in model has also been developed on a background of UGT1 $-/-$ mice thus eliminating the mouse background UGT1 levels (Section 19.8.3).

19.8.3 UGT1A (Combined Knock-In/Knock-Out) Mouse Models

A transgenic UGT1 knock-in model developed on a background of Ugt1 $-/-$ mice was developed by inserting human BAC encoding either normal (UGT1A1*1) or containing the mutation associated with Gilbert's syndrome (UGT1A1*28) into mice as transgenes [260]. Then, the knock-in transgenic mice were crossed with the heterozygous Ugt1 $+/-$ mice creating mice carrying the UGT transgene in a Ugt1 $+/-$ background. These mice were further interbred to establish Tg(UGT1A1*1)Ugt1 $-/-$ and Tg(UGT1A1*28)Ugt1 $-/-$ mice. The Tg(UGT1A1*28)Ugt1 $-/-$ mice encoded all nine of the UGT1A isozymes (UGTs1A1, 1A3, 1A4, 1A5, 1A6, 1A7, 1A8, 1A9, and 1A10), while the Tg(UGT1A1*1)Ugt1 $-/-$ mice were missing the *UGT1A8* gene.

The absence of UGT1A1 in the Ugt1 $-/-$ mice results in death within two weeks due to bilirubin toxicity [251]; however, the insertion of the human *UGT1A1* gene into the Ugt1 $-/-$ mice results in survival of the mice. This confirms the importance of UGT1A1 in the early developmental stages of bilirubin metabolism. In the less severe Gilbert's syndrome in humans, the promoter variant linked to the *UGT1A1**28 gene is hypothesized to result in reduced UGT1A1-RNA and protein in the liver [261,262], thus resulting in decreased bilirubin conjugation and mild hyperbilirubinemia. This hypothesized difference was observed in the Tg(UGT1A1*28)Ugt1 $-/-$ mice when compared to the Tg(UGT1A1*1)Ugt1 $-/-$ mice. The RNA levels for the liver-specific expression of UGT1A3, -1A4, -1A6, and -1A9 were similar for both transgenic mice, however, UGT1A1 RNA expression was more than sevenfold higher in the Tg(UGT1A1*1)Ugt1 $-/-$ mice when compared to the Tg(UGT1A1*28)Ugt1 $-/-$ mice. In contrast, expression levels of UGT1A1 in extrahepatic tissues (such as the small intestines) were similar between the Tg(UGT1A1*1)Ugt1 $-/-$ and the Tg(UGT1A1*28)Ugt1 $-/-$ mice showing the promoter polymorphism altered expression of UGT1A1 only in hepatic tissue. It was noted that the drop in total bilirubin during development mirrored the intestinal rather than the hepatic expression levels.

The impact of artificially increased total bilirubin was also evaluated in the transgenic mice utilizing phenylhydrazine to induce hydrolysis and spontaneously increase total bilirubin levels. The differential expression of UGT1A1 in the liver and small intestines of Tg(UGT1A1*28)Ugt1^{-/-} mice emphasizes the importance of understanding which organs are hypothesized to be affected in transgenic mice and to confirm expression levels of the enzyme of interest in multiple tissues of interest as expression levels could differ and lead to confounding results unless it is understood *a priori*.

Tg(UGT1A1*28)Ugt1^{-/-} mice have also been evaluated as a model to improve predictions of human UGT1A-dependent drug clearance in human subjects [263]. Pharmacokinetic and enzyme kinetic parameters were evaluated for three probe substrates in both Tg(UGT1A1*28)Ugt1^{-/-} [with and with phenobarbital (PB) treatment] and WT mice. The substrates evaluated were SN-38 (an exclusive UGT1A1 substrate [264]), ezetimibe (a partial UGT1A1 substrate [265]), and naloxone (a UGT2B7 substrate [266]). The UGT1A1 substrate SN-38 showed the largest difference in both drug exposure and clearance between the Tg(UGT1A1*28)Ugt1^{-/-} mice, Tg(UGT1A1*28)Ugt1^{-/-} mice treated with PB, and WT mice. The clearance of the UGT2B7 substrate (naloxone) was unaltered in the Tg(UGT1A1*28)Ugt1^{-/-} mice, which was as expected. Surprisingly, the pharmacokinetic parameters with ezetimibe showed small to no difference in the Tg(UGT1A1*28)Ugt1^{-/-} mice. The *in vivo* findings for SN-38, naloxone, and ezetimibe were consistent with the enzyme's kinetic parameters determined *in vitro* in WT, Tg(UGT1A1*28)Ugt1^{-/-}, and Tg(UGT1A1*28)Ugt1^{-/-} (treated with PB) mouse liver microsomes. They were also consistent with the enzyme's kinetic parameters determined using human liver microsomes without and homozygous for the UGT1A1*28 polymorphism. These findings suggest that glucuronidation by UGT1A1 may not play a major role in the overall metabolism of ezetimibe.

19.8.4 UGT Chimeric-HL Mouse Model

Chimeric-HL mice were developed using uPA/SCID mice [7], as previously mentioned in Section 19.3.3. These mice have been evaluated for their capacity to metabolize drugs catalyzed by either phase I [75] or phase II [267] enzyme systems. The UGT enzyme family was evaluated along with the other major phase II enzyme systems (SULT, NAT, and GSTs) in the livers of the chimeric-HL mice by mRNA, protein, and enzyme activity using RT-PCR, western blot analysis, and high performance liquid chromatography [267].

The mRNA expression of the evaluated UGT isozymes (UGT1A1, UGT1A9, and UGT2B7) increased in a concentration-dependent manner along with the positive control (human albumin). Further evaluation of the protein content for UGT1A1 and UGT2B7 also showed the specific UGT protein levels increasing in a concentration-dependent manner along with the human albumin. Since there are currently no specific substrates for UGT1A1, the specific enzyme activity of human UGT1A1 could not be measured in the chimeric-HL mice. However, UGT2B7 activity was measured using the probe substrate morphine and monitoring the formation of the 3- and 6-glucuronide metabolites. The ratios of UGT activity toward 3- and 6-glucuronidation in liver microsomes from mice, rats, guinea pigs, and rabbits has been shown to differ across species [268], thus indicating that this metabolic pathway may be of use in defining the human/mice enzymatic activity for UGT2B7 in the chimeric mice. In this

study evaluating the chimeric mice-HL [267], the morphine 6-glucuronidation activity in human liver microsomes was 36-fold higher than that of control mice. The UGT2B7 protein and morphine 6-glucuronidation activity in one chimeric mouse were 2.6- and 3.0-fold higher, respectively, than the corresponding protein content and activity of a human donor.

In addition, chimerical-HL mice developed using immunodeficient Fah-deficient mice repopulated with human hepatocytes have also been developed (Grompe mice) [8]. After pretreatment with a urokinase-expressing adenovirus, these mice were engrafted (up to 90%) with human hepatocytes. RT-PCR was performed on mRNA obtained from the chimeric-HL mouse livers and human UGT1A1 was evaluated and found to be abundantly expressed.

These results indicate the potential for chimeric-HL mice to be used for the study of human glucuronidation (with the most detailed information available for UGT2B7). However, additional characterization work using the chimeric-HL mice of interest should be conducted before specific use.

19.8.5 Other Mouse Models Affecting UGT (Brief Overview)

Transgenic animals developed to evaluate systems in addition to direct UGT models (UGT-null and knock-in models) have been shown to affect UGT activity. Specifically transgenic animals affect transcription factor-mediated UGT regulation such as nuclear hormone receptors, the AHR, and nuclear factor erythroid 2-related factor 2 (Nrf2) [259]. The nuclear hormone receptors and AhR models are covered in Section 19.10. This interconnectivity of receptors and enzyme systems bring forward an important point with regard to transgenic animals. Understanding downstream impacts of transgenic modifications and the impact on other systems is key to fully understanding the results obtained from transgenic animals.

19.9 SULFOTRANSFERASE

Sulfation is a conjugation reaction that serves to increase the polarity of molecules, enhancing the body's ability to excrete them. It is generally associated with the detoxification of xenobiotics, but it is also an important mechanism for the detoxification, regulation, or activation of many endogenous compounds, such as thyroid hormones and steroids [269]. Some compounds, such as morphine and minoxidil, exhibit enhanced pharmacological activity after sulfation [270–272], and it can also be a pathway to the bioactivation of some xenobiotics [273–279]. The enzymatic sulfation of -OH and -NH₂ groups of endogenous compounds or xenobiotics is accomplished by the action of cytosolic sulfotransferase (SULT) enzymes, a large gene family containing at least 11 subfamilies in humans [280]. All the SULTs require 5'-phosphoadenosine-3'-phosphosulfate (PAPS) as a cofactor supplying the sulfonyl moiety. The different SULT enzymes are expressed to varying levels in numerous tissues of the body. In humans, the most important SULTs for drug metabolism are SULT1A1, SULT1A3/4, SULT1B1, SULT1E1, and SULT2A1 [281]. SULT1A1 and 1B1 are active on a range of different substrates, but 1B1 has a higher K_m for most substrates [282,283]. SULT1A3 has a high selectivity for catecholamine substrates in primates [284,285]. SULT1E1,

also known as *estrogen-specific sulfotransferase* (EST), and SULT2A1 are selective for steroids, but also act on other xenobiotic compounds [286–288].

19.9.1 Sulfotransferase (Knock-Out) Mouse Model

SULT1E1 is important in the regulation of estrogen (17 β -estradiol), having an affinity for the substrate in the low nanomolar range. Sulfation of estrogen inhibits its binding to the estrogen receptor (ER), thus inactivating it. A line of SULT1E1 KO mice (SULT1E1 $-/-$) was generated by gene-targeting techniques [289]. Heterozygous chimeric mice from transfected ES cells were cross-bred to produce homozygous SULT1E1 $-/-$ -deficient mice. The absence of SULT1E1 activity was verified by northern and western blot and estrogen sulfotransferase activity assays. This line was used to investigate the reduced fertility observed in SULT1E1 $-/-$ mice [290]. The authors were able to demonstrate that the abnormally high estrogen levels associated with the absence of SULT1E1 not only impaired ovulation but also reduced the expression of COX-2. Administration of human chorionic gonadotropin improved the expression of COX-2, stimulating normal ovulation.

19.9.2 Natural Sulfotransferase-Deficient Animal Model

Brachymorphic mice are genetically deficient in the ability to synthesize PAPS due to reduced activity of ATP kinase [291]. These mice have been used to investigate the bioactivation of safrole in mouse liver [292]. An initial breeding stock of male brachymorphic mice was bred to B6C3F₁ females. Successive generations of mice were bred similarly, and bm/bm progeny were phenotyped by their shortened stature and dome-shaped skulls. After administration of [³H]-1'-hydroxysafrole to brachymorphic and normal mice, brachymorphic mice had 8–15% of the amount of liver DNA- and RNA-bound adducts as compared to their normal littermates. On the basis of the reduced incidence of hepatocarcinomas in the brachymorphic mice, the authors concluded that 1'-sulfooxysafrole is the ultimate electrophilic metabolite of 1'-hydroxysafrole. Other researchers have used this mouse model to investigate the activation of *N*-nitrosomethyl(2-hydroxyethyl)amine to a DNA alkylating agent [293], concluding that a sulfate intermediate is at least partially responsible for the observed carcinogenicity.

19.10 NUCLEAR HORMONE RECEPTOR (PXR, CAR, FXR, AND PPAR)

PXR, CAR, PPAR, and FXR were identified as novel orphan nuclear receptors of the nuclear receptor superfamily of ligand-activated transcription factors. These receptors function by forming a heterodimer with the retinoid X receptor α (RXR α , NR2B1). The nuclear receptor/RXR/ligand subsequently binds to a transcriptional response elements in the 5'-flanking region of the targeted gene resulting in the transcriptional activation [294–298]. The transcriptional factor/RXR/ligand complex works in concert to regulate the expression of specific genes that control the differentiation, development, homeostasis, and metabolism of the organism [295].

Various transcriptional factors regulate phase I and phase II metabolic enzymes and transporters that play a role in ADME of xenobiotics and endobiotics [299]. The development of GEMA can provide an *in vivo* tool to investigate the role of transcriptional

factors in the regulation of DMEs and transporters. Also, the GEMAs can facilitate the elucidation of receptor-independent/dependent pathways of drug-induced metabolism, toxicities, and role in mammalian development.

19.10.1 Pregnane X Receptor (PXR) (Knock-Out) Mouse Model

Two laboratories have generated mice lacking functional PXR [227,300] by disrupting the mouse *PXR* gene. The PXR KO/null mouse (*PXR*^{-/-}) developed by Staudinger *et al.* [300] replaced the first coding exon (amino acids 1–63) with a neo resistance cassette by homologous recombination, which resulted in a *PXR* transcript ~200 bp shorter than the native transcript. This resulted in a nonfunctional *PXR* gene response. The laboratory of Xie *et al.* [227] developed a *PXR*^{-/-} mouse by deleting two exons (amino acid residues from 63 to 170 of the DNA-binding domain), generating a nonfunctional *PXR* gene. The *PXR*^{-/-} mice generated by these two methods were viable and fertile with no overt biochemical alterations in levels of cholesterol, steroid hormones, triglycerides, albumin, free bilirubin, and bile acids. More recently, it was found that PXR activity is required for normal femoral bone mineral density development as its absence manifests in a phenotype known as *hypophosphatemia* [301], based on studies conducted in *PXR*^{-/-} mouse. In addition, as discussed briefly above, the *PXR*^{-/-} animal model has been utilized to confirm the role of PXR in the expression of DMEs such as cytochrome P450s, UDPGA glucuronyl transferases (UDPGTs), sulfotransferases, PAPS, and drug transporters such as P-glycoprotein (P-gp), breast cancer resistance protein (BCRP), organic anion polypeptide transporter (Oatp2) [300,302–306]. Additionally, it was assumed that PCN induced the activity of Cyp3a11 via PXR activation; however, CYP3a11 mRNA was increased ~fourfold in the *PXR*^{-/-} mice compared to WT mice suggesting that PXR may actually play a repressive role [300]. However, the *PXR*^{-/-} mouse generated by Xie *et al.* [227] exhibited a different response phenotype in which it did not respond to PCN and the basal levels of CYP3a11 were not higher than that in the WT mice. Thus, slight changes in the removal of PXR amino acid sequences appear to lead to varying gene regulations in response to inducers.

The effects of PCN via PXR activation do extend beyond xenobiotic-metabolizing enzymes in which CYPs involved in cholesterol and bile acid formation are modulated such as CYP7a1 [300]. It has been shown that PCN exposure can reduce the activity of Cyp7a1, the enzyme involved in the metabolism of cholesterol to bile acids. The role of PXR in regulating Cyp7a1 has been elucidated via studies conducted in the *PXR*^{-/-} mice in which KO animals showed a twofold less basal activity and were refractory to PCN treatment compared to WT animals [300]. In addition to modulating enzyme activity, PXR can activate the transporter Oatp2, which transports bile acids, and is inducible by PCN. Interestingly, Staudinger *et al.* [300] have shown that bile acids can directly upregulate PXR, specifically. PXR is activated by lithocholic acid (LCA), a toxic secondary bile acid associated with cholestasis. LCA via PXR can stimulate the expression of Cyp3a11 and Oatp2, which then work in concert to rid excess bile salts from the body [227,300]. In these studies, PXR is required for the expression of CYPs (Cyp7a1 cited as an example) and can provide a protective mechanism to modulate LCA-induced toxicities.

PXR as a drug target has been proposed to enhance circulating levels of the anti-cancer drug paclitaxel [307]. Paclitaxel, a microtubule-binding drug, can activate both mouse and human PXR, resulting in the activation of DMEs and drug transporters

at the transcriptional level to accelerate its own metabolism following chronic dosing [308,309]. In the WT mouse, chronic dosing of paclitaxel resulted in a 31% and 59% decrease in AUC and $C_{\max}$, respectively, on day 5 compared to day 1 consistent with PXR-mediated induction [310]. In contrast, paclitaxel administered to PXR $-/-$ mouse showed an increase in drug exposure with chronic dosing. In humans, ketoconazole has been shown to modulate paclitaxel biotransformation by inhibiting CYP3A4 and CYP2C8 activity as well as by inhibiting MDR1-related transport [307]. More recently, it has been shown that ketoconazole can inhibit PXR activation [308]. It has been proposed that ketoconazole binds to the outside of the PXR ligand-binding pocket based on mutagenesis studies conducted in the AF-2 region of PXR. Consequently, ketoconazole appears to repress the activity of PXR, which in turn can alter the metabolic enzyme and transport activities dependent on this transcriptional factor.

19.10.1.1 PXR Humanized (Knock-In/Knock-Out) Mouse Models. Species differences in CYP induction in response to various inducing agents have been well documented. Comparison of PXR sequences from different species (mouse, rat, rabbit, and human) shows ~95% similarity in their DNA-binding domains; however, it shares only 80% amino acid similarity in the ligand-binding domain (LBD) [311]. In human and rabbits, PXR is sensitive to Rif pretreatment but is insensitive in mouse and rat, while PCN can induce CYP3A activity in rat and rabbit and modestly in mouse but has no effect in humans [311]. The utility of WT and PXR $-/-$ mouse models have provided insight toward the potential of ligands to induce PXR, however, extrapolation to humans is limited due to species differences in response to drugs such as Rif, clotrimazole, PB, and troglitazone [311]. Because of the species differences in response to PXR ligands, a humanized PXR mouse model provides a more appropriate *in vivo* model to identify and evaluate potential human hPXR Pxr $-/-$ inducers. Several humanized PXR mouse models have been reported. The two models are Alb-hPXR and BAC-hPXR [227,312] in which human PXR gene is expressed in the absence of the mouse Pxr. The activity of these humanized PXR animal models were confirmed by treatment with Rif and PCN. The humanized animal model responded to Rif pretreatment and did not respond to PCN. The humanize PXR model provides a tool to anticipate potential drug interactions involving PXR, minimizing untoward reduction in drug efficacy as a result of enhanced metabolic or transport clearance of the drug. Also, such animal models can identify ligands that may repress PXR activity resulting in increased toxicity risks due to elevated drug levels [313]. In summary, the humanized PXR mouse models provide researchers with an *in vivo* tool to elucidate the role of PXR in many disease states and modulation of xenobiotic DMEs and transporters.

19.10.2 CAR

The nuclear CAR has been shown to increase and decrease the regulation of genes sensitive to PB [314–316]. Similar to PXR, CAR plays a role in the regulation of xenobiotic drug metabolism enzymes and transporters. In response to PB exposure, CAR translocates to the nucleus, forms a heterodimer with the RXR, and activates the 51-bp PB-responsive enhancer module conserved in the mouse, rat, and human CYP2B genes [314,317–320]. Drug-metabolizing and transporter proteins modulated by PB are CYP1A2, CYP2B1, CYP3A, CYP4A10, CYP2E1, UGT1A1, GST, MRP2, BCRP, and OATP1B1, and suppresses CYP2E1 [315,321–323].

19.10.2.1 CAR (Knock-Out) Mouse Model. On the basis of cDNA microarray analysis, CAR appears to play both an activating and repressing role in the regulation of DMEs. For example, Cyp2b1 was induced by PB in the WT mice and induction was absent in CAR-null mice [316]. However, Ueda *et al.* [316] found that CYP4a10 is induced by PB in the null CAR mouse compared to WT suggesting that the presence of CAR represses protein expression in the presence of an inducer. In addition to elucidating the role of CAR in drug clearance, the CAR-null mice model has helped identify proteins involved in drug-induced hepatotoxicities. For example, APAP (250 mg/kg)-related hepatotoxicity was observed in WT mice pretreated with 1,4-bis[2-(3,5-dichloropyridyloxy)] benzene (TCPOBOP), a CAR agonist, while CAR-null mice showed no such hepatotoxicities [323]. It was found that TCPOBOP treatment modulated proteins involved in APAP-induced toxicity such as Cyp2e1, Cyp1a2, Cyp3a11, and GST. Specifically, TCPOBOP modestly suppressed Cyp2e1 mRNA levels but induced Cyp1a2, Cyp3a11, and GST mRNAs in WT animals, while these genes were not altered in the CAR-null mice.

Additionally, the CAR-null mice have helped elucidate enzymes involved in physiological regulation of bilirubin homeostasis. Five enzymes have been identified to mediate the *in vivo* levels of bilirubin [324]. In systemic circulation, bilirubin is noncovalently bound to hAlb. It has been postulated that only free bilirubin enters hepatocytes by a facilitated diffusion mechanism likely involving hepatic uptake transporters as organic anion polypeptide transporter 1B1. Once bilirubin is inside the hepatocyte, it readily binds to GST (A1 or A2), which reduces its efflux from the hepatocyte to the blood [324]. In hepatocytes, bilirubin is cleared from the body by UGT1A1. Bilirubin diglucuronide is formed in the liver and is secreted across the bile canalicular membrane by an active transporter, multidrug-resistance-associated protein 2 (MRP2, ABCC2). Complete loss of UGT1A1 function leads to severe hyperbilirubinemia, a condition known as the *type 1 form of Crigler-Najjar syndrome*, a fatal disease rescued only by liver transplantation [325], and a defect in MRP2 results in the accumulation of the conjugated bilirubin, a disease known as *Dubin-Johnson syndrome* [326]. In humans, PB treatment has been known to increase bilirubin conjugation activity and decrease elevated bilirubin levels [327]. Because PB induction is regulated by CAR, it has been associated to play a role in bilirubin clearance. Huang *et al.* [324] showed that WT mice pretreatment with TCPOBOP showed an increase in hepatocyte expression of OATP1B1, UGT1A1, GSTA1, GSTA2, and MRP2, the five enzymes involved in bilirubin elimination, while induction was absent in CAR-null mice.

It has been reported that PXR, like CAR, can also regulate the expressions of bilirubin-detoxifying enzymes and transporters [324,328]. However, in cell cultures that did not contain PXR ligands, PXR was shown to suppress the ability of CAR to induce MRP2 [329]. A double null mouse line (2XENKO) lacking CAR and PXR showed that both receptors contribute to the protective response to the hydrophobic bile acid LCA [330], protecting against LCA toxicity. Furthermore, the double KO mice model has shown that CAR and PXR function coordinated to regulate both xenobiotic and bile acid metabolism [331].

As for transporters, CAR regulates the expression of several transport proteins such as P-gp, BCRP, MRP2, MRP4, OATP1B1, and bile salt export pump (BSEP) [332,333]. Among these transporters, the CAR-null mouse has been applied to understand P-gp, MRP2, and MRP4 [334,335]. In the presence of dexamethasone and PCN, CAR ligand and activators, MRP2 expression was not present in hepatocytes isolated from null

CAR mouse compared to WT mice [335]. It has been shown that Mrp4 can transport sulfated bile acids. Under normal conditions, hepatic levels of sulfated bile acids are low but are increased under cholestatic conditions. Assem *et al.* [334] hypothesized that the upregulation of Mrp4 during cholestasis is a compensatory mechanism to protect the liver from accumulation of bile acids. Additionally, Sult2a1, an enzyme that conjugates a sulfate to hydroxyl bile acids and steroids, is also involved in the protection of the liver from bile acid accumulation. It was shown that CAR is required to coordinately upregulate hepatic Mrp4 and Sult2a1. It was shown that Sult2a1 is down-regulated in Mrp4-null mice, which highlighted relation between *Mrp4* and *Sult2a1* gene expression.

19.10.2.2 Humanized (Knock-In/Knock-Out) CAR Mouse Model. Species differences in response to ligands activating CAR have been observed. A transgenic mouse specifically expressing hCAR but not mouse CAR in the liver has been constructed [323]. The utility of a “humanized” CAR animal model provides an *in vivo* tool to identify ligands sensitive to human CAR activity. The humanized CAR model was validated with pretreatment to PB as increased sensitivity to APAP toxicities was observed based on elevated mRNA levels of *Cyp1a2*, *Cyp3a11*, and *Gstpi* [323]. Meclizine, an antiemetic agent, is an example to highlight species differences in CAR response [336]. In WT mice, meclizine was shown to induce the expression of *Cyp2b10*, *Cyp3a11*, and *Cyp1a2*, target genes of CAR. In contrast, in humanized CAR animals, meclizine treatment in primary hepatocytes isolated from the liver of humanized CAR mice showed suppression of *Cyp2b10*, *Cyp3a11*, and *Cyp1a2* gene expression. Moreover, it was shown that meclizine can suppress APAP-induced hepatotoxicity as the CYP responsible for forming the reactive metabolite of APAP is not expressed. In summary, the humanize CAR animal models provide insight toward the disposition of compounds when species differences in substrate selectivity and response may occur. The utility of the humanized model provides an *in vivo* system to evaluate the induction potential of new drug entities involving human CAR.

19.10.3 Peroxisome-Proliferator-Activated Receptors

PPARs play a role in the control of xenobiotic metabolism, lipid metabolism, glucose homeostasis, adipocyte differentiation, and inflammation [337–341]. As mentioned above, there are three different PPAR isoforms: PPAR α , PPAR β/σ , and PPAR γ . PPARs regulate gene expression by binding, as heterodimers with RXRs to specific PPAR response elements in the promoter regions of specific target genes. In the absence of a ligand, high affinity complexes are formed between the PPAR–RXR heterodimer [342]. These three receptors are present in most tissues in humans and rodents; however, protein levels are highly variable. PPAR α has been associated with fatty acid metabolism and gluconeogenesis [343–346]. It has been shown that tissue-specific expression profile of PPAR α in humans is very different from that in rat and mouse. Specifically, human liver contains lower levels of PPAR α in contrast to the rodents, in which potent peroxisomal proliferators can cause liver tumors due to activation of the gene [347–349]. In human livers that express PPAR α , levels are approximately one order of magnitude lower than mouse liver. Human cDNA for PPAR α does not encode a functional protein because it lacks exon 6 due to alternate RNA splicing, this was observed in all 10 human liver samples examined [350]. In animals, PPAR α

is associated with the upregulation of CYP4A6 (fatty acid omega hydroxylase) [351]. PPAR α is the receptor for the fibrate drugs that lower triglycerides and raise high density lipoprotein cholesterol levels in the treatment and prevention of coronary artery disease [352,353].

PPAR γ plays a critical role in adipocyte differentiation and is the receptor for the glitazone class of insulin-sensitizing drugs used in the treatment of type 2 diabetes and management of dyslipidemia [354]. PPAR γ activates genes that increase glucose and lipid uptake, enhances glucose oxidation, and lowers free fatty acid levels and insulin resistance [355]. It is highly expressed in fat, but is low in the liver, and has trace levels in the muscle tissues [356]. The thiazolidinediones (TZD) are synthetic ligands of PPAR γ . In patients with type 2 diabetes, TZD had been shown to decrease mean glycated hemoglobin [HbA(1c)] by 1.5% and lower HbA(1c) to less than 7% in 30% of patients [356]. Other indications for PPAR γ include cell cycle control by inhibiting growth and/or inducing differentiation of several cancer types, such as prostate, breast, pancreatic, and colon [357] and in neurodegenerative disorders such as AD [358,359].

PPAR β/σ is involved in fatty acid oxidation in muscle tissues, inflammation, and oxidative stress [356]. Persistent low level of inflammation is believed to contribute to several metabolic diseases such as obesity, type 2 diabetes mellitus, and atherosclerosis [360]. By activating PPAR β/δ genes, this appears to reduce the production of inflammatory cytokines by adipocytes and prevents fatty acid-induced inflammation in skeletal muscle cells. Also, gene activation appears to minimize the development of cardiac hypertrophy and suppresses macrophage-derived inflammation in atherosclerosis [360].

19.10.3.1 PPAR (Knock-Out) Mouse Model. The ability to oxidize fatty acids is necessary for the normal response to fasting as demonstrated by severe hypoglycemia in which premature death was observed in fasted PPAR α -deficient (PPAR $-/-$) mice. PPAR $-/-$ mice have a defect in fatty acid metabolism but have normal reproduction capabilities. Gemfibrozil, a lipid-lowering agent, can activate PPAR α . Studies conducted in PPAR $-/-$ mouse model have shown that this receptor plays a key role in lipid homeostasis and is important in the regulation of fatty acid oxidation enzymes. CYP4A isoforms are under the control of PPAR α , in which starvation and diabetes can triggers its upregulation [361]. PPAR α is required for the fasting-activated expression of target genes involved in mitochondrial and extramitochondrial fatty acid oxidation in liver and heart, tissues known to increase fatty acid oxidation rates during short-term starvation. Studies in the PPAR $-/-$ mice have shown that CYP4A contributes to the cellular metabolic response to fasting. In the fasting state, endogenous lipids activate PPAR α that induces several genes involved in fatty acid oxidation, due to either increase fatty acid uptake and/or utilization. *trans*-4-Hydroxy-2-nonenal (HNE) is a potent cytotoxic and genotoxic compound originating from the peroxidation of n-6 polyunsaturated fatty acids [362]. Studies conducted in WT mice and PPAR α -null mice have confirmed the role of CYP4A in the metabolism of HNE. In the presence of an inducer, clofibrate, WT mice were able to form the two metabolites derived from HNE; however, PPAR α - $-/-$ mice did not form them [362].

PPAR γ , in both rodents and humans, is highly expressed in adipose tissue, where it is a major regulator of adipogenesis, and lower expression levels are found in skeletal muscle and liver [363]. KO mice engineered with a deletion of muscle PPAR γ have been utilized to elucidate the physiologic role of muscle PPAR γ and elucidate the mechanism of the diabetic drugs known as TZDs in response to insulin [364]. Norris

et al. [364] found that these mice develop excess adiposity as well as whole-body insulin resistance. Tissue-specific insulin sensitivity in these mice was normal in skeletal muscle but impaired in the liver and possibly in adipose tissue. Unlike PPAR α that is activated by fibrates to upregulate the activity of CYP4A family, not as much is known for PPAR γ . However, studies utilizing DMBA, a tumor initiator, suggests that PPAR γ plays a protective role in carcinogenesis. This was exemplified in studies conducted with heterozygous PPAR γ mouse models, as a null model does not exist, since this gene is necessary for normal development and null mice die *in utero* around gestational day 10 [365]. In the heterozygous PPAR γ mice, an increase in DMBA-mediated skin tumors was observed compared to the WT animals. Studies with CYP1B1 $-/-$ mice have shown that this enzyme appears to have a protective role in skin tumor formation compared to WT mice [366]. Taken together, PPAR γ may regulate CYP1B1-mediated bioactivation of DMBA to its carcinogenic metabolites [367].

19.10.3.2 Humanize PPAR (Knock-In/Knock-Out) Mouse Model. When species difference in activity exists, humanized animal models are ideal to evaluate gene response in the presences of ligands. As previously discussed, PPAR α exhibits species differences and it has been shown that humans retain the capacity to encode PPAR α but a portion of the gene lacks exon 6 producing nonfunctional receptor and the mRNA levels are 10 times lower than the levels present in rodents [368,369]. The humanized PPAR α mouse that was generated by introducing human PPAR α transgene into a PPAR α $-/-$ mouse did not manifest hepatocellular proliferation when exposed to fibrates unlike that observed in WT mouse. The utility of humanized PPAR α mice would aid in the understanding of the response differences and enable better management of drug development risks in moving a PPAR α agonist forward [370].

19.10.4 Farnesoid X-Activated Receptor

The FXR, also known as the *bile acid receptor*, plays a role in the regulation of bile acids, lipid, and glucose homeostasis [371,372]. The receptor is expressed primarily in the liver, kidney, intestine, and adrenal gland [373,374]. As mentioned above, the FXR heterodimerizes with RXR and binds to farnesoid X-activated receptor response elements (FXREs) within the regulatory regions of target genes [374]. Bile acids function as ligand activators for both rodent and human FXR [375]. Chenodeoxycholic acid (CDCA) and cholic acid, primary bile acids, are synthesized in the liver from either cholesterol or oxysterols and then transported across the basement membrane of the hepatocyte into the bile canaliculi and stored in the gallbladder [376]. Bile acids excreted into the intestinal lumen can be further metabolized by bacteria into secondary [deoxycholic acid (DCA) or LCA] or tertiary bile acids before their resorption in the distal ileum. Bile acid concentrations are controlled by a feedback regulatory pathway in which the activation of the FXR represses transcription of both the *CYP7A1* gene, which encodes the rate-limiting enzyme in the synthesis pathway, and the *CYP8B1* gene required for synthesis of cholic acid [377]. Various diseases are attributed to defects in this cycle. Examples are cholestasis (impaired bile flow) that leads to hepatic accumulation of toxic bile acids such as LCA and 3-keto-LCA as well as toxins that would normally be excreted in the bile [378]. FXR is activated by various bile acids such as CDCA, DCA, LCA, and cholic acid [379]. In response to bile acids, FXR regulates several transport proteins and metabolizing enzymes involved in bile

acid homeostasis such as Ntcp, the hepatic basolateral sodium taurocholate cotransporter protein [380], Bsep, the hepatic canalicular BSEP transporter [381], and CYP7a, a cholesterol 7 α -hydroxylase [382].

19.10.4.1 FXR (Knock-Out) Mouse Model. In evaluating the mechanistic role of FXR in bile acid regulation, the development of FXR KO mouse (FXR $-/-$) model has provided an *in vivo* tool to assess its role. A FXR $-/-$ mouse has been engineered by Sinal *et al.* [124], in which the animals were visibly normal, exhibited normal physiological developmental characteristics, and were indistinguishable from WT littermates. However, FXR $-/-$ animals could not control bile acid synthesis and excretion. These animals have been utilized to study the effects of dietary bile acid, namely, 1% cholic acid (added to animals food), and have confirmed that FXR is essential in regulating bile acid homeostasis as high systemic levels can lead to severe wasting, dyslipidemia, and hypothermia and even death (30% of the null mice by day 7) [124]. Organ-specific FXR $-/-$ mouse models have been generated in which activity in the liver or intestine has been disrupted [383]. Kim *et al.* [383] showed that FXR intestinal deletion or liver deletion models provide a mechanistic tool to understand organ-specific FXR-mediated regulation and whether there are potential interplay between intestinal and liver FXR activity in the regulation of bile acid homeostasis. It was shown that treatment with a FXR-selective agonist GW4064 significantly repressed CYP7A1 levels in FXR liver-deficient mice but had no effect in the FXR intestinal deficient mice. In contrast, it was shown that FXR-mediated repression of CYP8B1 was dependent on liver FXR and less dependent on intestinal FXR. Thus, the different organ-specific expression of FXR provided a valuable tool to demonstrate that FXR-related repression of bile acid synthesis requires the complementary actions of FXR in both liver and intestine and enabled the mechanistic understanding of the role of CYP7A1 and CYP8B1 in maintaining bile acid homeostasis [383].

19.10.5 Multiple Nuclear Receptor GEMA

As discussed above, PXR and CAR play critical role in the transcriptional regulation of phase I and II enzymes as well as transporters. There are unique substrates as well as overlapping substrates with different affinities to PXR and CAR that contribute to the induction of a wide array of genes involving cross talk between the nuclear receptors and transcriptional cofactors [384]. Enzymes and transporters such as CYP3A, CYP2B, UGT, SULT, GST, P-gp, MRPs, and OATPs, which contain the responsive element (PXRREs) and PB-responsive element (PBREMs) in the promoter region can be regulated by both PXR and CAR [385]. To evaluate the complex mechanisms governing the cross talk between PXR and CAR, Scheer *et al.* [385] generated a variety of possible combinations of PXR and CAR mouse lines. Mouse models generated were (i) humanized PXR and CAR KO, (ii) PXR KO and humanized CAR, (iii) PXR KO and CAR KO, and (iv) humanized PXR and CAR. The utility of these mouse models provide a tool to discriminate between the PXR- and CAR-mediated effects of these two receptors. For example, PB is reported to activate PXR *in vitro* and studies with humanized PXR and CAR animals suggest that the PB-mediated activation of Cyp3a11 and Cyp2b10 *in vivo* is CAR dependent [385]. This example highlights a disconnect between *in vitro* and *in vivo* responsiveness to PXR and CAR. Moreover, PB did not induce the expression of mouse Cyp3a1 and Cyp2b10 in humanized PXR and CAR

KO mice, which demonstrates that human PXR is not able to compensate for the loss of CAR activity [385]. The above examples demonstrate how the use of combination animal models of CAR and PXR can elucidate the dependence or lack of dependence of these transcription factors in the regulation of genes that may affect drug disposition and toxicity in humans.

19.10.6 Aryl Hydrocarbon Receptor (AHR)

The AHR has been studied for its pathological activity in response to man-made environmental toxins/pollutants such as halogenated PAHs. AHR is distinct from the nuclear receptor superfamily in that it is a ligand-activated transcriptional factor. It is found in the cytosol and is normally present in the inactive form associated with a chaperone complex consisting of two molecules of heat shock protein-90, the immunophilin-like X-associated protein 2 (XAP2), and p23. AHR is highly conserved and expressed in various cell types. AHR is a member of the basic-helix-loop-helix (bHLH) superfamily of DNA-binding proteins [386–388]. In the cytosol, AHR is activated on ligand binding resulting in the dissociation from its inactive complex formation and translocates to the nucleus where it dimerizes with the Ah receptor nuclear translocator protein (ARNT) resulting in gene transcription. The genes transcriptionally regulated are *CYP1A1*, *CYP1A2*, *CYP1B1*, xanthine oxidase, xanthine dehydrogenase, *GST-Ya*, and *UDPGT* [387,389–391]. A variety of lipophilic toxins such as TCDD, B[a]P, and naphthalene have been shown to mediate the toxic response through the AHR regulation of various CYP enzymes [389,392–396].

19.10.6.1 AHR (Knock-Out) Mouse Model. AHR-deficient mouse (*Ahr*^{−/−}) are typically generated by homologous recombination in ES cells [397]. *Ahr*^{−/−} animals from different labs where exon 1 or 2 has been deleted have shown that the receptor is critical in embryonic and physiological development, as abnormal development of the liver, heart, spleen, thymus, and kidney occurs in these animals [390,397–399]. The lack of AHR receptor resulted in age-related organ lesions that appear nine months postbirth. Other effects observed were cardiomyopathy (CMP; 100%) with hypertrophy, focal fibrosis, and T-cell deficiency only in their spleens, while other lymphoid organs were not immune compromised [400]. In humans, the expression of the AHR in the left ventricle specimens obtained from explanted hearts of patients with CMP based on immunohistological analysis revealed significantly increased AhR levels in the diseased heart. Weak to intermediate staining of anti-AhR was observed in control hearts (hearts from healthy accident victims) but weak to intense staining in CMP hearts [401].

Ahr^{−/−} mice failed to induce drug-metabolizing genes that encode enzymes that catalyze the metabolism of foreign compounds. This is exemplified by studies with TCDD and B[a]P in which *AhR*^{−/−} mice were resistant to TCDD-induced immune suppression and showed reduced tumor formation in the presence of B[a]P, due to low expression levels of cytochrome P450 1A1 (*CYP1A1*) required to activate these carcinogens to reactive metabolites [395,402–404]. The *Ahr*^{−/−} mice has been utilized to understand the role of Ahr in the immune system as phenotypic differences exist among the different KO mice lines. For example, the *Ahr*^{−/−} mice [397] are more susceptible to infections with *Helicobacter hepaticus*, an opportunistic infection associated with immunodeficiency [405]. It has been speculated that *CYP1B1* may metabolize B[a]P to benzo[α]pyrene-4,5-epoxide, the resultant mutagen in mice resulting in B[a]P-induced

carcinogenesis. Moreover, unlike the *Ahr*^{-/-} mice, the expression of CYP1A1 and 1B1 mRNAs in liver and lung were highly induced in WT mice by several PAHs such as 7,12-dimethylbenz[a]anthracene, dibenz[a,l]pyrene, 3-methylcholanthrene, 1,2,5,6-dibenzanthracene, benzo[b]fluoranthene, and benzo[a]anthracene [393]. The role of CYP1B1 in B[a]P-induced carcinogenesis was elucidated in which *Ahr*^{-/-} mice had lower levels of this enzyme compared to WT animals.

19.10.6.2 Humanized AhR (Knock-In/Knock-Out) Mouse Model. The large inter- and intraspecies differences in the susceptibility to dioxin-induced toxicities are due to the species differences in AhR receptor [406]. The humanized AhR mouse model was generated by knock-in strategy via homologous recombination in which the human *AHR* gene is transcribed under the same regulatory mechanism as the replaced murine gene [406]. The humanized AHR mouse model affords an *in vivo* model to evaluate human AHR-induced gene responses in the presence of toxins. The affinity of human AHR to TCDD is 10-fold lower compared to mouse AhR [393]. The humanized mouse studies have provided evidence that impaired receptor ligand binding is associated with *in vivo* toxin resistance due to the lower affinity of human AHR [406]. Since ligand affinity differs in rodents and humans, the humanized AHR model ensures that strong ligands for human AHR are anticipated.

19.10.6.3 AHR Chimeric Mouse Model. A transgenic C57BL/6J mice containing Han/Wistar *Ahr* gene (endogenous mouse *Ahr* gene was eliminated) provides an animal model to further evaluate the molecular mechanisms governing aryl hydrocarbon enabled toxicities [407]. The Han/Wistar rats are resistant to TCDD toxicity due to a mutation in the *Ahr* gene, in which altered splicing of the *Ahr* mRNA results in two *Ahr* proteins. The two proteins consist of a deletion (DEL) and insertion (INS) variants, with the latter dominating in expression. The laboratory of Pohjanvirta [407] showed that the transgenic INS mouse were phenotypically normal except for increase in testes weight. For drug metabolism properties, the INS mouse responded to TCDD induction similar to WT mice; however, sex differences in response to TCDD were not observed as both sexes showed resistance to TCDD toxicities. It has been observed that the *Ahr* is capable of associating to the ER, resulting in modulation of ER trans-activation function. Specifically, the development of reproductive organ tumors such as breast cancer often depends on the action of sex hormones. Further, PAHs can be activated the *Ahr*/Arnt heterodimer, which directly associates with the ER subtypes “a” and “b.” This association results in recruitment of unliganded ER and coactivator p300 to estrogen-responsive gene promoters, leading to activation of transcription and estrogenic effects in the absence of estrogen [408]. This INS transgenic mouse model provides tools to evaluate PAH-related toxicities related to body weight, testicular function, and hormone-dependent diseases.

19.11 DRUG TRANSPORTERS IN DISPOSITION

19.11.1 Multidrug Resistance

The ATP-binding cassette (ABC) transporter P-gp protein was discovered in the mid-1970s for its ability to confer multidrug resistance in tumor cells [409]. It is an integral

membrane transporter in humans encoded by the *MDR1* (*ABCB1*) gene [410]. *MDR1* gene is expressed in various human tissues and the protein serves as a permeation barrier in the gastrointestinal tract and brain, while contributing to the elimination of drugs in the liver and kidneys. It is localized to the apical surface of intestinal epithelial cells, bile canaliculi, renal tubular cells, and placenta and on the luminal surface of capillary endothelial cells in the brain and testes [411]. Humans carry a single *MDR1* gene, while rodents contain two genes specifically *mdr1a* and *mdr1b* [412–415]. In rodents, the two *mdr* genes are expressed together in liver, kidney, heart, lung, and spleen and independently in different organs where mouse *mdr1a* is expressed in the intestinal epithelium, blood–brain barrier (BBB), and blood–testis barrier, while *mdr1b* is expressed in the adrenal gland and ovaries [416].

19.11.1.1 P-gp (Knock-Out) Mouse Model. To better understand the role of P-gp in barrier tissues such as the gastrointestinal tract and the BBB, *MDR1* knock-out/null animal models were generated to understand the role of this transporter. Mice deficient in either *mdr1a* or *mdr1b* (*Mdr1a/b*–/–) have been generated. The *mdr1a* KO (*Mdr1a*–/–) mouse was generated first in which the *mdr1a* gene was disrupted in which fragments of exon 6 and 7 were replaced by hygromycin phosphotransferase cassette. For the *Mdr1b* knock (*Mdr1b*–/–) mouse, fragments from exon 3 and 4 were deleted. In both mice models, both showed that disruption of the *mdr1a* or *mdr1b* gene did not affect animal viability and these animals exhibit normal development and were fertile giving rise to normal size litters [410,417]. In *Mdr1a*–/– mouse, as discussed previously, this protein is highly expressed at the BBB. Studies with *Mdr1a*–/– mice showed that ivermectin and vinblastine brain levels were 87- and 22-fold greater than their WT counterparts following a 0.2-mg/kg oral dose of ivermectin and a 1-mg/mg IV dose of vinblastine, respectively [410]. Similarly, studies conducted with nelfinavir demonstrated that *mdr1a* in the BBB can limit drug access in which brain levels were elevated 36-fold in the *mdr1a*–/– model, while plasma levels increased only 2.5-fold in WT [418]. The *Mdr1b*–/– mice showed slightly elevated [³H]digoxin levels in the adrenal glands (632 vs 320 ng/g tissue) and ovaries (708 vs 288 ng/g tissue), while all other tissues were no different in [³H]digoxin exposure compared to WT mice [419]. A double KO mice of *mdr1a*–/– and *mdr1b*–/– has also been produced. These animals were developmentally normal with no overt abnormalities [419]. To understand the pharmacokinetic ramifications of having both *mdr1a* and *mdr1b* genes absent, studies were conducted in which double KO animals were intravenously administered 1-mg/kg [³H]digoxin. Tissue exposure in the double KO mice resemble the *mdr1a*–/– mice with increased levels observed in the brain and testis (male animals) after 4 h postdose, which suggested that the *mdr1a* is the dominant phenotype [419].

After oral administration, plasma concentrations were elevated two- to fivefold in *mdr1a*–/– mice and with IV administration, brain concentrations were elevated 7- to 36-fold. These data demonstrate that P-gp limits the oral bioavailability and penetration of these agents into the brain. The double KO mouse provides a tool to understand the mechanistic role of P-gp in barrier tissues as well as in excretory organs such as the liver and kidney. Studies with *mdr1a/b*–/– double KO animals showed that compounds that are not known to cross the BBB exhibit tremendous increase on exposure in the brain such as asimadoline [420]. Also, the *mdr1a/b*–/– mice and WT animals have been utilized to elucidate the sedating and nonsedating effects of H1 antagonists. For example, the first-generation H1 antagonists such as diphenhydramine, triprolidine,

and hydroxyzine are known as *sedating* and cause somnolence, while the second-generation H1 antagonists such as cetirizine, loratadine, and fexofenadine produce very little somnolence or CNS effects [421]. Using the *mdr1a/b*^{-/-} double KO mice, Chen *et al.* [421] were able to demonstrate that the nonsedating antihistamines were substrates for P-gp with brain to plasma ratios between 2 and >14 compared to brain to plasma ratio observed in WT mice. In contrast, the nonsedating antihistamines exhibited brain to plasma ratios ~1.

Mdr1a/b^{-/-} animals are a useful tool to identify P-gp as a factor of brain uptake and to assess whether comedices may limit CNS exposure; however, extrapolation of brain exposure from animal data to humans is poor. For example, the brain to plasma concentration ratio of nelfinavir increased 7- to 36-fold, paclitaxel increased 6- to 28-fold, and verapamil increased 8.5-fold in *mdr1a/b*^{-/-} mice compared to WT [422]. In rat studies, where cyclosporine (CsA) is coadministered as a P-gp inhibitor, the brain to plasma ratio of verapamil increased 24.1-fold [423]. Studies in humans utilizing noninvasive positron emission topography (PET) imaging techniques have provided a tool to measure P-gp activity based on drug exposure in the brain. In human healthy volunteer study, [¹¹C]verapamil, 0.2 mCi/kg, was intravenously infused to patients for 1 min before and after a 1-h infusion of CsA (2.5 mg/kg/h) [424]. The brain to plasma ratio of [¹¹C] radioactivity increased by 79% at a measured blood concentration of 2.8 μ M CsA, which is much less than the brain exposures observed in rodent models. Hsiao *et al.* [425] conducted a P-gp drug interaction study with verapamil and CsA, where CsA doses were administered to achieve a range of systemic concentrations ranging from 0 to 12 μ M. The authors showed that drug levels achieved in rodent brain far exceed the levels achieved in human brain. However, when CsA was dosed in rodents to achieve brain concentrations similar to the levels observed in humans, similar brain to blood exposure of [³H]-verapamil was observed in the rodents of ~75% [425].

19.11.1.2 Dog *MDR1* Model. The mouse *Mdr1* KO model is derived from experimental manipulations of the *MDR1* gene. As an alternative model, a dog collie model exists in which a mutation in the *MDR1* gene leads to inactive P-gp activity. Specifically, a frame shift deletion of 4 bp results in a premature stop codon leading to nonfunctional P-gp protein in which the dogs show sensitivity toward ivermectin-induced neurotoxicity [426]. Studies demonstrated that the *Mdr1*-deficient dog models are comparable to the mouse *Mdr1a/b* models in the distribution patterns of loperamide and ivermectin, thus providing a nonrodent model to investigate *Mdr1* gene [426,427].

19.11.2 Breast Cancer Resistant Protein

BCRP is a member of the ABC family of drug transporters. It can actively transport various anticancer drugs such as doxorubicin, mitoxantrone, camptothecin, and topotecan from cells, causing multidrug resistance [428–431]. Like P-gp, BCRP is localized on the apical membrane and found in barrier tissues such as the gastrointestinal tract, blood placenta and brain barriers, and in eliminating organs such as the liver and very low levels in the kidney [432].

19.11.2.1 *Bcrp* (Knock-Out) Mouse Model. The *Bcrp* KO (*Bcrp*^{-/-}) mouse was developed by deleting a large portion of the ATP-binding domain in exons 3–6 and

replaced with a 1.8-kb pgk-hygro cassette in reverse-transcriptional orientation. The Bcrp^{-/-} mice were developmentally normal and fertile, with similar lifespan as the WT animals [433]. The first application of Bcrp^{-/-} mice was in the evaluation of skin photosensitivity to porphyrins, namely, pheophorbide a and protoporphyrin. Pheophorbide a is a phototoxic porphyrin catabolite of chlorophyll. Animals ingest a vast amount of food products containing chlorophyll and Bcrp is known to transport pheophorbide a. Bcrp is known to reduce the bioavailability of pheophorbide a from the diet by preventing its uptake from the intestine and possibly effluxing it via liver and kidney [433]. Phototoxicity has not been observed in WT mice but bcrp^{-/-} mice show extreme hypersensitivity ~100-fold more sensitive toward pheophorbide a compared to WT mice.

Since BCRP is present at the BBB, it is believed to limit CNS exposure of many drugs. Of interest are the human immunodeficiency virus 1 (HIV) nucleoside reverse-transcriptase inhibitors (NRTIs) that exhibit low CNS penetration due to active efflux at the BBB. Zidovudine (AZT) and abacavir (ABA) are *in vitro* substrates for BCRP [434]. Utilizing the Bcrp^{-/-} KO animals has helped identify the role of this transporter in plasma exposure and brain penetration. Studies were conducted with AZT and ABA in WT and Bcrp^{-/-} KO mice in which no difference in either area under the concentration–time profiles for plasma (AUC_{plasma}) or brain (AUC_{brain}) were observed for AZT between the WT and Bcrp^{-/-} mice. However, for ABA, brain exposure in the Bcrp^{-/-} mice was 1.5-fold greater than WT mice [435]. These results indicate that BCRP may not play a role in CNS exposure for AZT but appears to contribute for ABA.

19.11.3 Multidrug Resistance Protein

The MRP transporter family consists of nine members. Among these transporters, MRP1, MRP2, MRP3, and MRP4 have been widely investigated and associated with the transport of xenobiotics and endogenous substances [436]. Typical substrates for MRPs are organic anions, for example, anticancer and antiviral drugs conjugated to GSH, glucuronate, or sulfate and endogenous substrates as bile salts, bilirubin glucuronides, prostaglandins, and leukotrienes [437–452]. These MRPs are associated with drug resistance in which the mechanism of action requires a constant supply of GSH to form GSH conjugate in the cell so that conjugated drug is then transported out of the tumor by these transporters [439]. Tissue distribution of the MRPs are broad, where MRP1 is ubiquitous except low levels in liver; MRP2 is predominately expressed in the liver, kidney, and gastrointestinal tract; MRP3 is predominately found in the liver, kidney, adrenals, and gastrointestinal tract; and MRP4 is most abundantly expressed in the kidney, brain, and prostate [439,449,451,453]. In humans, MRP2 deficiency leads to a mild liver disease known as the *Dubin-Johnson syndrome*.

19.11.3.1 *Mrp1 and Mrp2 (Knock-Out) Mouse Model.* MRP1 KO (Mrp1^{-/-}) animal models have been constructed by Lorico *et al.* [454] in which the mouse *Mrp* gene in W9.5 ES cells was disrupted by replacing a small segment of the ATP-binding domain with a neomycin resistance gene cassette. The Mrp1^{-/-} mice subsequently generated from this modification were viable and fertile and appeared healthy without any developmental alterations. After western blot analysis, the *Mrp* gene was absent in the colon, lung, and muscle in the Mrp1^{-/-} mice, tissues that normally express

high levels. Also, plasma levels and tissue levels of GSH in the *Mrp1*^{-/-} mice were elevated, where tissue levels increased by 25–90% and most pronounced in tissues that express Mrps in the WT state [454]. The utility of the *Mrp1*^{-/-} mouse model has been used to explore the role of *Mrp1* in anticancer-mediated cytotoxicity and drug resistance. Several investigators have shown that the *Mrp* gene affords protection against the toxic effects of agents such as etoposide, vincristine methotrexate, and arsenite in which compounds exhibited toxicities twofold or greater in *Mrp1*^{-/-} mouse compared to WT mouse based on LD₅₀ values, bone marrow toxicity as a result of depletion of nucleated cells, and poor leukocyte count recovery [439,454,455]. Moreover, dose tolerance to toxicity for etoposide was lower in the *Mrp1*^{-/-} mice in which maximum tolerated dose was 125 mg/kg compared to 200 mg/kg in WT mice [455].

MRP2 is localized in the apical membrane of epithelial cells in hepatocytes, renal proximal tubules, and enterocytes [456]. *Mrp2*-deficient mouse models have been described by several laboratories in which *Mrp2* gene has been disrupted by the insertion of a Lac-Neo cassette [457] or insertion of a 2-kb pgk-hygro cassette to delete exons 4–6 [458]. The *Mrp2*^{-/-} mice showed normal development, was fertile, and exhibited a lifespan similar to WT mice [457]. However, Chu *et al.* [457] reported that total bilirubin levels were fivefold higher and conjugated bilirubin was 60% of total bilirubin (conjugated and unconjugated) in the *Mrp2*^{-/-} mice compared to WT animals. Vlaming *et al.* [458] observed a 20–25% increase in liver weight in adult *Mrp2*^{-/-} mice compared to WT mice [457,458]. It was also observed that the suppression of *Mrp2* resulted in the upregulation of liver *Mrp4* levels by six- to sevenfold in liver and 2.5-fold in kidney and *Oat1* levels in the kidney by 2.5-fold [457]. The utility of the *Mrp2*^{-/-} mouse has elucidated the role of *Mrp2* in various tissues. *Mrp2*^{-/-} mice exhibit reduced intestinal secretion, biliary secretion, and renal elimination. This was demonstrated by a significant reduction in the excretion of GSH and bilirubin glucuronides in *Mrp2*^{-/-} mice compared to WT [457]. In another example, mycophenolate mofetil (MMF), the prodrug of mycophenolic acid (MPA), is widely used to prevent allograft rejection in solid organ transplantation and as an immunomodulator in the treatment of autoimmune diseases [459]. In humans, MPA is taken up by the liver, undergoes glucuronidation to MPA-glucuronide, is excreted into the bile, and is deconjugated by gut bacteria to MPA. The coadministration of CsA in patients taking MPA resulted in less biliary secretion of MPA-glucuronide and reduced systemic exposure of MPA compared to patients coadministered tacrolimus and MPA. Unlike CsA, tacrolimus is not an inhibitor of MRP2 and therefore did not alter MPA disposition [460,461]. To clarify the role of P-gp and *Mrp2* in MPA pharmacokinetics, the evaluation of MPA and its glucuronide in *Mdr1a/b*^{-/-} and *Mrp2*^{-/-} animals provided insights toward CsA-mediated drug interaction. Following oral MMF administration, the coadministration of CsA resulted in the expected changes in MFA levels in WT, *Mdr1a/b*^{-/-}, and *Mrp2*^{-/-} mice but MFA-glucuronide increased in both KO animals indicating that P-gp and *Mrp2* cannot account completely for the effect of CsA [462]. In the clinical setting, MMF is monitored for potential drug transporter interactions.

19.11.3.2 Rat MRP2 Model. Two natural mutant rat strains for *Mrp2* are the TR and Eisai hyperbilirubinemic rat (EHBR), these are spontaneous mutants of the Wistar and Sprague-Dawley strains, respectively [463,464]. The main differences between the normal rodent versus the mutant *Mrp2* rodent is decreased bile flow, increased plasma levels of bilirubin glucuronides, decreased biliary secretion of reduced GSH,

and decreased elimination of GSH, glucuronide, sulfate conjugates, and unconjugated compounds [465]. These rat strains lacking functional Mrp2 have been utilized to examine the role of this transporter in the efflux of conjugated bilirubin; however, it has been noted that Mrp3 and UGT1a are upregulated in these Mrp2-deficient animals [457].

19.11.3.3 Mrp3 (Knock-Out) Mouse Model. MRP3 is localized in the basolateral membrane of epithelial cells in hepatocytes and enterocytes [456]. Several Mrp3-deficient (Mrp3^{-/-}) mice have been constructed by disrupting a segment in exons 2–8 of the *Mrp3* gene with a hygromycin resistance gene [466] or deletion of 2.1-kb fragment in exons 6–8 of the *Mrp3* gene [467]. The Mrp3^{-/-} mice showed normal development, were fertile, and exhibited a lifespan similar to WT mice. The transport of taurocholate in Mrp3^{-/-} and WT mice were similar. However, it does appear that Mrp3^{-/-} mice exhibit lower plasma bilirubin glucuronide levels. Because Mrp3 preferentially transports glucuronide conjugates, the role of Mrp3 in drug disposition has been investigated for drugs such as APAP, morphine, and etoposide [466–468]. The disposition of APAP is predominately mediated by glucuronidation and sulfation with minor contribution by cytochrome P450 to form the reactive metabolite that is detoxified by conjugation to GSH [469]. Following an IV dose of APAP, no differences were observed in the formation of the APAP-GSH and APAP-sulfate conjugates but large differences were observed in APAP-glucuronide conjugate in Mrp3^{-/-} and WT mice. A 20-fold higher accumulation of APAP-glucuronide was found in the liver of Mrp3^{-/-} mice and 10-fold reduction in biliary secretion of this conjugate [470]. Moreover, Manautou *et al.* [470] reported that Mrp3^{-/-} mice are more resistant to APAP hepatotoxicity than WT mice, which is most likely a result of the faster repletion of hepatic GSH, as the Mrp3^{-/-} mice had approximately threefold greater GSH. Thus, results obtained from the Mrp3^{-/-} mice model provided direct evidence that Mrp3 appears to be the only basolateral transporter that can efficiently secrete APAP-glucuronide into the blood from hepatocytes [470]. Another utility of the Mrp3^{-/-} mice model provided direct information of the sensitivity of *Mrp3* gene to protect normal tissues from the cytotoxicities of anticancer agents such as etoposide. Further, etoposide drug resistance occurs in human cancer patients so studies conducted in Mrp3^{-/-} provide mechanistic insight toward drug resistance [447]. The Mrp3^{-/-} mice did not show sensitivity toward etoposide toxicity as no difference in LD₅₀ was observed among Mrp3-deficient and WT animals. Unlike the Mrp1^{-/-} mouse model that did show sensitivity to cytotoxicity and lower dose toleration, Mrp3^{-/-} did not show this effect, suggesting that etoposide sensitivity and drug resistance may be more attributed to Mrp1 function.

19.11.3.4 Mrp4 (Knock-Out) Mouse Model. The tissue localization of MRP4 is not uniform as it is found at the apical membrane of the proximal tubules [451], the basolateral membrane of hepatocytes [471], the basolateral membrane of the choroid plexus epithelium, and the apical membrane of the endothelial cells of the brain capillaries [472]. Mrp4-deficient (Mrp4^{-/-}) mice have been generated in which exon 27 was disrupted in murine ES cells by replacing it with a neomycin resistance cassette via homologous recombination [472]. The generated Mrp4^{-/-}-deficient mice showed normal development and fertility and exhibited a lifespan similar to WT mice. The role of MRP4 in drug disposition has been evaluated with several anticancer and antiviral agents. Specifically, Mrp4 has been shown to have functional involvement in the renal

elimination of adefovir, tenofovir, and cidofovir [473]. These compounds were administered by constant IV infusion. Plasma levels of adefovir was higher in Mrp4^{-/-} mice compared to WT; however, kidney concentration of adefovir and tenofovir was almost twofold greater in Mrp4^{-/-} mice, which reflects an inability of the proximal tubules that efflux the drug from the proximal tubules to the urine. No significant differences were observed for cidofovir between Mrp4^{-/-} and WT animals, indicating that its pharmacokinetics are not dependent on Mrp4 activity. In another example with topotecan, the pharmacokinetics were compared between Mrp4^{-/-} and WT mice following IV administration [472]. The pharmacokinetic concentration–time profile was similar in the two animal models, exhibiting a biphasic elimination; however, at 6 h postdose, topotecan plasma levels were 50% higher in the Mrp4^{-/-} animals. Other observations were (i) 36% lower topotecan excretion in the urine and (ii) brain concentrations were sixfold higher in Mrp4^{-/-} mice compared to WT. Topotecan was shown to be a substrate for Mrp4 and localization of Mrp4 at the choroid epithelium appears to play a role in limiting drug penetration into the cerebral spinal fluid (CSF). The Mrp4^{-/-} mice models provide the *in vivo* evidence that Mrp4 plays a role in protecting the brain from cytotoxins [472].

19.11.4 Organic Anion Transporting Polypeptides

OATP transporters consist of a superfamily of proteins [474]. The OATPs are sodium-independent uptake transporters involved in the transport of anionic drugs in clinical use as well as endogenous substrates such as bile acids, hormones, and steroids [436,475]. OATPs are expressed in several organs involved in drug disposition such as intestine, liver, kidney, and brain [476]. The OATPs are highly expressed in the sinusoidal membrane of hepatocytes or in the apical membrane of enterocytes, where they may affect liver penetration or intestinal uptake, respectively [474]. Several OATPs are of interest in specific organs such as OATP1A2 in the intestine and OATP1B1, OATP1B3, and OATP2B1 in the liver. Inhibition of the hepatic uptake transporters may lead to significant drug interactions, as observed for several statins such as pravastatin and fluvastatin [477,478].

19.11.4.1 *Oatp* (Knock-Out) Mouse Model. OATP1B1 and OATP1B3 can play the role of a rate-limiting step to the hepatic uptake of many drugs. In rodents, there is only one member of the Slco1b family, known as *Slco1b2* (*Oatp1b2*) in both rats and mouse that corresponds to human OATP1B1 and 1B3 [479–481]. Several laboratories have generated *Slco1b2* KO (*Oatp1b2*^{-/-}) mice models in which one model was produced by deletion of exons 10–12 of the mouse *Oatp1b2* gene sequence and insertion of a neomycin resistance cassette [482] and the second one by disruption in intron 1 through part of intron 3 [483]. Both methods revealed that the absence of these genes did not alter normal development and fertility and no apparent phenotypic abnormalities were observed. In all cases, the expression levels of *Oatp1b2* mRNA in the liver were markedly lower or absent in comparison to WT mice. Zaher *et al.* [482] also reported sex differences in expression of other *Oatps* in the *Oatp1b2*^{-/-} animals compared to WT mice. In male *Oatp1b2*^{-/-} mice, *Oatp1a4* and *Oatp2b1* were unaltered compared to WT, although *Oatp1a1* was greater in the KO animal. In female *Oatp1b2*^{-/-}, no difference was observed for *Oatp1a1*, but KO mice exhibited greater expression of *Oatp1a4* and *Oatp2b1* [482]. Additionally, Lu *et al.* [483] also reported

similar alterations in the Oatps as Zaher *et al.* [482] and also noted that KO mice exhibited moderate conjugated hyperbilirubinemia. In general, the Oatp1b2^{-/-} KO mice lack expression of Oatp1b2 but expressions of non-Oatp transporters and DMEs were comparable to WT mice [484].

The Oatp1b2^{-/-} animal model provides a tool to gain insight toward the *in vivo* relevance of human OATP1B1 and OATP1B3 to the hepatic uptake of substrates. Lu *et al.* [483] showed that the organic anionic dye dibromosulfophthalein disulfonate, a compound that is actively taken up by Oatps in the liver and largely biliary excreted, is eliminated more slowly in the Oatp1b2^{-/-} mice compared to WT mice. In studies evaluating Rif and lovastatin acid, significantly higher liver to plasma partition ratio ($K_{p,liver}$) or liver uptake were observed in WT compared to the Oatp1b2^{-/-} mice consistent with reduced expression of the liver uptake transporter in the KO animals [484]. Consistently, Zaher *et al.* [482] conducted a single IV study with rifampin (1 mg/kg) and observed a 1.7-fold increase in plasma AUC in the Oatp1b2^{-/-} mice and the $K_{p,liver}$ was reduced by fivefold, and nearly eightfold when assessed at steady-state conditions after 24 h of continuous subcutaneous infusion compared to WT mice. Also pharmacokinetic studies with pravastatin showed fourfold lower $K_{p,liver}$ in the Oatp1b2^{-/-} mice compared to WT mice [482]. Thus, the pharmacokinetic results observed in the Oatp1b2^{-/-} mice were in line with expectations of an animal model lacking a critical hepatic uptake observed for compounds that are actively taken up by the liver.

19.11.4.2 Oatp (Multiple Knock-Out) Mouse Model. It is widely known that for the OATP there are no ortholog genes between rodents and humans. In some cases, there appears to be substrate overlap among rodents and humans despite the lack of orthologs. For example, humans express only a single OATP1A member (OATP1A2), while rats and mice express several members (Oatp1a1, 1a4, 1a5, and 1a6), believed to have risen by gene duplication events. In contrast, humans express OATP1B1 and OATP1B3, while rodents express only Oatp1b2 [485,486]. The generation of a double KO animal lacking *Slco1a* (*Oatp1a*) and *Slco1b* (*Oatp1b*) genes (Oatp1a/1b^{-/-} mice) would enable the further understanding of these Oatps in drug disposition. van de Steeget *al.* [486] generated this double KO mice model by insertion of loxP sites at both ends of the *Slco1a/1b* gene cluster (~620 kb), followed by Cre-mediated deletion. The double KO mice were developmentally normal and fertile and exhibited a normal lifespan comparable to WT animals. However, both male and female Slco1a/1b^{-/-} mice had significantly increased body weights, and by 85 weeks, they exhibited hyperbilirubinemia compared with WT mice.

van de Steeget *al.* [486] examined the pharmacokinetics of MTX in the double KO animals (Slco1a/1b^{-/-}) to understand the role of these two Oatps in the *in vivo* disposition of MTX, a known substrate for OATP1A/1B family. Plasma MTX levels were 4.8- and 3.8-fold elevated in the double KO mice compared to WT, respectively, following IV and oral doses of MTX (10 mg/kg). Additionally, the accumulation of MTX in WT animals was 50% of the MTX dose, while the Slco1a/1b^{-/-} mice showed only 2% accumulation of the dose. Similarly, the metabolite of MTX, 7-hydroxy MTX, was reduced in Slco1a/1b^{-/-} mice compared to WT, which highlights that lower uptake of drug in the liver results in less metabolism. These studies with MTX clearly highlight the contribution of Oatps toward the elimination of drugs.

19.11.4.3 Humanize OATP (Knock-In/Knock-Out) Mouse Models. As discussed above, orthologous *OATP* genes between rodents and humans do not exist. For example, nafcillin, a β -lactam antibiotic, is a substrate for rat *Oatp1a4*; however, in humans, both OATP1B1 and OATP1B3 contribute to liver uptake. Studies conducted with human *in vitro* OATP1B1 and OATP1B3 transfected cell lines have shown that nafcillin is a substrate for both transporters, but OATP1B3 is the primary uptake transporter [487]. The utility of a mouse KO model enables pharmacokinetic evaluation to assess the role of *Oatps* in the disposition of a compound. It is important to note that the lack of orthologous genes among rodent to human can make translation or predictions from animals to humans difficult. Thus, the creation of OATP1B1 humanized mouse models provide improved tools to explore the pharmacokinetic contribution of human transporters toward a compound's disposition [488]. From immunohistochemical staining, OATP1B1 was localized in the liver with no expression found in the intestine or kidney. van de Steeg *et al.* [488] used these humanized OATP1B1 mice (*Oatp1a/1b* were KO) to explore the *in vivo* role of human OATP1B1 in the disposition of the anticancer drug MTX. Following IV administration of MTX, the AUC was 1.5-fold less in the humanized OATP1B1 mice, but liver concentrations were twofold higher compared to WT mice. Thus, the humanized OATP1B1 mice model affords an *in vivo* tool to assess the role of human OATPs toward the disposition of a new chemical entity as both a substrate and an inhibitor.

19.11.5 Organic Cation Transporters

Organic cation transporters (OCTs) mediate the transport of hydrophilic, low molecular weight organic cations in organs such as the intestines, liver, kidney, and brain. OCT mediate the uptake of both endogenous (e.g., DA and choline) and exogenous (e.g., cimetidine, metformin, cisplatin, ranitidine, and procainamide) substrates that are positively charged at physiological pH [436]. There are three members of the OCT family (OCT1, OCT2, and OCT3). OCT1 is broadly distributed with highest expression in the liver and less expression in small intestine, kidney, and lung. OCT2 is highly expressed in the kidney and less expressed in small intestine, lung, and brain. OCT3 is broadly distributed in several tissues such as skeletal muscle, kidney, placenta, and heart and to a lesser extent in the liver [489]. Among these OCTs, OCT1 and OCT2 have been well characterized for substrates and inhibitors. The OCTs are facilitative diffusion transporters that in principle can transport cations in both directions and operate independently of H^+ and Na^+ gradients. The driving force determining the direction of transport is provided by the concentration gradient of the transported substrate and by the membrane potential [490]. The clinical relevance of the OCTs has been identified in which (i) OCT1 contributes to hepatic uptake affecting drug disposition and efficacy; (ii) OCT2 contributes to renal uptake, which may affect renal clearance and potential drug interactions; and (iii) both transporters are associated with genetic polymorphisms [491].

19.11.5.1 Oct (Knock-Out) Mouse Model. Several OCT KO animal models have been constructed. OCT1 is localized at the basolateral membrane of epithelial cells in the liver, kidney, and intestine in the rodent and is primarily expressed in the liver of humans [492]. This transporter facilitates the uptake of hydrophilic cationic

compounds into the liver. The OCT1 KO mice model was constructed by disrupting the mouse *Oct1* gene by replacing exon 7 [493]. The Oct1 KO mice (Oct1^{-/-}) were developmentally normal and fertile. These animals have been utilized to investigate the pharmacologic and physiologic role of Oct1 in the liver, intestine, and kidney by comparing the pharmacokinetics of tetraethyl ammonium ion (TEA) following an IV administration in the Oct1^{-/-} and WT animals. In rodents, Oct1 is highly expressed in the above organs. Consistent with the uptake role of Oct1, Oct1^{-/-} mice accumulated four- to sixfold less TEA in liver, twofold less direct intestinal excretion of TEA, but 1.5-fold greater excretion of TEA in the urine compared to WT mice [493]. The authors hypothesized that the increase in urinary excretion of TEA in the Oct1^{-/-} mice was likely due to a secondary effect of limited liver uptake as 20% of the administered dose accumulates in the liver of WT animals compared to only 3% of the dose in the Oct1^{-/-} animals.

19.11.5.2 *Oct1 and Oct2 (Double Knock-Out) Mouse Model.* Other OCT KO animals have been generated such as Oct2 KO (Oct2^{-/-}) and double KO of Oct1 and Oct2 (Oct1/2^{-/-}) [494]. For the Oct2^{-/-} mice, the model was generated by disrupting exon 1 with a replacement with an inverted *pgk-neo* cassette via homologous recombination in ES cells. To generate the double KO animals, Jonker *et al.* [494] started with Oct1^{-/-} ES cells in which *Oct2* gene was disrupted by removing exon 1. By western blot, excised liver and kidney showed no detectable levels of Oct1 and Oct2 in the double KO animals and Oct2^{-/-} animals lacked Oct2 in the kidney. Oct2^{-/-} and WT mice were dosed intravenously with TEA, a substrate for Oct2, but no difference in compound accumulation in kidney, liver, and plasma were observed, indicating that the absence of Oct2 plays a minor role in TEA disposition. However, in the double KO animals, TEA plasma levels were ~fourfold greater and the accumulation of TEA in the kidney and liver were approximately fourfold lower than in WT animals. Thus, the advantage of the double KO animals provides evidence that both genes contribute to the distribution and excretion of the compound.

19.11.6 Organic Anion Transporters

Organic anion transporters (OATs; SLC22A family) consist of 10 members but most clinical interest lies with OAT1 and OAT3. The OATs mediate the transport of hydrophilic, low molecular weight organic anions in kidney (OAT1 and OAT3) and brain (OAT3) [436]. OATs mediate the tissue distribution of a wide variety of small and hydrophilic organic anions of endogenous (e.g., bile salts, taurocholate, and cortisol) and exogenous origins (e.g., cimetidine, adefovir, AZT, ciprofloxacin, and furosemide) that are negatively charged at physiological pH [436,491]. OAT1/3 functions as organic anion exchanger. The OATs require an energy source that is several steps upstream, which is derived from a Na⁺/K⁺-ATPase pump that creates an Na⁺ gradient across the plasma membrane. Then an Na⁺/dicarboxylate cotransporter protein moves dicarboxylic acids (such as glutarate and ketoglutarate) against its electrochemical gradient, which creates an outwardly directed gradient that enables the uptake of an organic anion into the cell. Therefore, when one molecule of an organic anion is transported into a cell by an OAT exchanger, one molecule of an endogenous dicarboxylic acid is simultaneously transported out of the cell [495]. The clinical relevance of the OATs has been linked to nephrotoxicities with therapeutic

agents such as adefovir and cidofovir [496]. To minimize nephrotoxicity, probenecid, an OAT inhibitor, has been coadministered with cidofovi, which inhibits the tubular accumulation [497].

19.11.6.1 Oat (Knock-Out) Mouse Model. Several OAT KO animal models have been constructed. OAT1 is localized at the basolateral membrane of epithelial cells in the kidney, choroid plexus, and olfactory mucosa [498,499]. A 52-base segment within the coding region of exon 1 of *OAT* gene was disrupted by homologous recombination with a cassette encoding β -galactosidase and a neomycin-selectable marker (LacZ-Neo), which results in the inability to transcribe or translate the gene [500]. The *Oat1* KO (*Oat1*^{-/-}) mice of both sexes were viable and fertile, and they appeared healthy without any developmental alterations. In WT animals, expression levels of *Oat1* mRNA and protein levels are higher in male animals compared to female animals and greater renal transporter activity is observed in the male animals [500]. Pharmacokinetic studies were conducted to elucidate the role of *Oat1* in the disposition of furosemide. Following an IV dose of furosemide, the renal excretion of furosemide was diminished in the *Oat*^{-/-} animals compared to WT confirming that the renal secretion of furosemide is mediated by *Oat1* activity.

An *Oat3* KO (*Oat3*^{-/-}) mouse model has been generated by replacing exon 3 of the murine *Oat3* gene, with an inverted neomycin cassette via homologous recombination in CJ-7 ES cells [499]. The *Oat3*^{-/-} of both sexes were viable and fertile, and they appeared healthy without any developmental alterations and appear to live longer than WT animals [499]. The utility of *Oat3*^{-/-} mouse has helped clarify its role in the uptake of PAH, which was presumed to be transported by *Oat1*. In a pharmacokinetic study, low levels of PAH were excreted in the urine of *Oat3*^{-/-} animals compared to *Oat1*^{-/-} and WT animals [499,500].

19.11.7 Bile Salt Export Pump

The BSEP is considered to be a sister of P-gp [501], a member of the ABC superfamily of transporters. This transporter is considered a major transporter involved in the biliary excretion of bile salts. BSEP is expressed in the apical membrane of hepatocytes and responsible for bile salt-dependent bile flow. The clinical significance of BSEP is associated with the finding that mutations in this gene result in a form of progressive familial intrahepatic cholestasis (PFIC), also known as *PFIC type II* [325].

19.11.7.1 Bsep (Knock-Out) Mouse Model. A KO mouse model for *Bsep* has been constructed by disruption of the gene. A 1.4-kb fragment of the ATP-binding domain was replaced with neomycin-resistant cassette. The subsequent *Bsep*-deficient mouse (*Bsep*^{-/-}) was viable and fertile but displayed growth retardation [502]. Other physiological observations with the *Bsep*^{-/-} mice were 20% lower body weight than WT mice. The utility of the *Bsep*^{-/-} mice model provides an *in vivo* model to confirm the role of *Bsep* in the biliary excretion of bile salts in which its accumulation in the liver is one of several mechanisms for cholestasis. [¹⁴C]-Taurocholate was infused in *Bsep*^{-/-} and WT mice, and impaired secretion of radioactivity was observed 30 min following dosing in the KO animals (5% compared to 66% for WT) and accumulation in the liver was 70% compared to 2% for WT [502]. Additionally, total concentration of bile salts in the *Bsep*^{-/-} animals was reduced by fourfold and total bile salts in the liver and

plasma were elevated 4- and 5.8-fold, respectively, compared to WT animals. Also, the secretion of hydrophobic bile salts such as deoxycholate and chenodeoxycholate were statistically different between Bsep^{-/-} and WT animals but not for hydrophilic bile salts such as ursodeoxycholate, muricholate- ω , and muricholate- β . Taking this together, Bsep is the main transporter of hydrophobic bile salts and secretion of the hydrophilic bile salts appears to be mediated by a compensatory transporter.

Because Bsep does not efflux all the bile salts, Bsep^{-/-} mice exhibits mild cholestasis [502] unlike humans, where a mutation in BSEP can lead to fatal cholestatic disease [503]. Wang *et al.* [504] observed elevation of Mdr1a and 1b expression in Bsep^{-/-} mice. A triple KO mice model lacking Mdr1a, Mdr1b, and Bsep were generated by Wang *et al.* [504]. The triple KO animals showed histological changes typical of cholestatic stress, such as jaundice, limited bile flow in early adulthood, and signs of hepatic inflammation. More specifically, bile flow was reduced by 73% and bile salts accumulated by 50% in the liver of the triple KO animals but not in the WT animals. The studies conducted with the triple KO clearly demonstrate that the mild cholestasis observed in Bsep^{-/-} was the result of upregulation of murine Mdr1a and 1b, which compensated for the reduction in biliary clearance of hydrophobic bile salts as the triple KO mice demonstrated a severe cholestatic phenotype. As a note of caution, Bsep^{-/-} animal models exemplify the danger in utilizing KO animals to gain further insight toward a mechanism, as upregulation of compensatory proteins may occur, which may obscure the true role of a protein of interest. One of the key points is the observation that Bsep^{-/-} mice did not exhibit the severe form of cholestasis as that observed in humans.

19.12 CONCLUSION

GEMA have provided a means to gain new insights and validate mechanisms, disposition, and consequences of exposure to drugs or toxins. Specifically, the role of DMEs, transcriptional factors, and transporters have been further elucidated to understand activation and detoxification mechanisms that govern the toxicities of a molecule. The examples given in section 19.5 illustrate the importance of the enzyme in forming intermediates that can be further metabolized to toxic products which otherwise is thought of as a detoxification step. Many of the examples, however, illustrate the complexity of drug disposition processes in which most enzymes and transporters are relatively nonselective and promiscuous. Moreover, feedback mechanisms are present to rebalance homeostasis, which may upregulate parallel processes that make it difficult to achieve unequivocal conclusions. GEMAs provide a mechanistic tool to gain an overall assessment of the potential role of DMEs, transcriptional factors, and transporters as well as evaluate the potential interplay of these systems; however, species differences poses a challenge to truly predict potential outcomes in humans. While it is unlikely that GEMAs will become a routine tool in preclinical drug development, they do provide a tool to answer some specific questions and provide bespoke solutions (such as in section 19.11.1 and ATP-binding cassette transporter and intestinal and brain permeability). Overall, the animal models in research and drug development have provided enormous insight and validated mechanisms to provide greater understanding of the role of DMEs, transcriptional factors, and transporters in the absorption, disposition, metabolism, and drug-related toxicities.

1 Introduction: An Overview of the Role of Metabolism in Drug Toxicity

SIDNEY D. NELSON

Department of Medicinal Chemistry, School of Pharmacy, University of Washington,
Seattle, WA, USA

Up until the 1960s, the metabolism of drugs and other chemicals was primarily associated with detoxication processes. In fact, the first major monograph on the metabolism of drugs and other chemicals was written by R. Tecwyn Williams and appeared in 1947 under the title *Detoxication Mechanisms—The Metabolism of Drugs and Allied Organic Chemicals* [1]. This landmark book in the field of drug metabolism was followed by others that were widely used as texts and reference guides, which highlighted the basic enzyme systems involved in drug metabolism and the chemical structural groups affected. *Fundamentals of Drug Metabolism and Drug Disposition* by La Du *et al.* [2] and a two-part series entitled *Drug Metabolism: Chemical and Biochemical Aspects* and *Concepts in Drug Metabolism, Part B* by Bernard Testa and Peter Jenner are now classics in the field [3,4].

Since the 1980s, essentially every monograph in the area of drug metabolism has incorporated concepts of reactive metabolites and drug toxicity, and drug interactions and drug toxicity [5–8]. Some monographs have been primarily devoted to these concepts because in several instances, metabolism-based toxicities have caused human morbidity and mortality and limit the development and use of drugs and other chemicals that otherwise may be very beneficial [9]. Some of the earliest work on the characterization of reactive metabolites as mediators of toxicity were carried out in the 1950s during the investigations on mechanisms of chemical carcinogenesis by the Millers (see Ref. 10 for a review of this early work). Meanwhile, in approximately the same time period, the first case reports of drug interactions that caused drug toxicities appeared (see Ref. 11 for a proceedings report of these early cases).

Reactive metabolite-based drug toxicities came to the forefront with the now classic series of papers published in the late 1970s by researchers led by Jerry Mitchell, Jim Gillette, and B. B. Brodie in the Laboratory of Chemical Pharmacology of the National Heart, Lung, and Blood Institute at the NIH on the bioactivation of the widely used analgesic/antipyretic drug, acetaminophen, to a reactive metabolite that caused hepatotoxicity [12–15]. Thousands of research papers, many book chapters and reviews, and even a book have since been published on the mechanism of liver injury caused by this drug (for more recent reviews, see Refs 16–19). Several other examples of reactive metabolite formation from drugs leading to toxic effects in animals

and humans soon followed, and biological reactive intermediates have been the subject of numerous symposia and symposia proceedings. One of the most recent of these provided data showing that drug toxicity is now responsible for approximately one-third of the terminations of drug candidates in development and that over 70% of those cases were related to drug metabolism [20].

Although reports of drug interactions leading to toxicities have appeared since the early 1950s [21], drug interactions did not receive serious attention until the publication of *Drug Interactions: Clinical Significance of Drug Interactions and Drug Effects on Clinical Laboratory Results* by Hansten in 1971 [22]. The public did not really take note until the discovery in the early 1990s that inhibition of cytochrome P450 3A4 caused cardiac toxicity and death in patients taking the antihistamine, terfenadine [23–25]. This resulted in the issuance of new guidelines in 1997 by the FDA and other regulatory agencies worldwide, stipulating the need for *in vitro* drug interaction studies as part of the safety assessment of new drugs. Since then, books have been published on mechanisms of drug interactions [7].

The chapters in this volume of this encyclopedia represent an update on the multiplicity of chemical and biological factors that are involved in both reactive metabolites and their role in drug toxicities and in drug interactions. Box 1.1 is a brief synopsis of some of the major factors that are discussed. Drug structure plays a significant role, in that it determines the structures of metabolites that can be formed by a cadre of enzymes that can catalyze a wide variety of reactions on organic chemicals. The chapters titled *Bioactivation I: Bioactivation by Cytochrome P450s*, *Bioactivation II: Phase I (Non-P450)*, *Bioactivation by Phase-II-Enzyme-Catalyzed Conjugation of Xenobiotics*, *Safety Testing of Drug Metabolites: A Practical Approach for the Implementation of the MIST Guidance in PKDM*, *In Vitro Toxicity Screening in Early Drug Discovery: Importance of Metabolism and Reactive Metabolites* describe the mechanisms of formation of drug metabolites with a focus on bioactivation mechanisms and the various enzymes that catalyze the reactions. The chapter titled *Stereochemical Elements Associated with Drug Metabolism and Toxicity* describes specific examples where the stereochemistry of a drug and its metabolites play a significant role in drug toxicities and drug interactions. It is important for the reader to understand that all drug-metabolizing enzymes can form products that can cause toxicities depending on the drug structure, which when coupled to the particular reaction catalyzed, defines the structure of the metabolite.

BOX 1.1 SEVERAL IMPORTANT DETERMINANTS OF DRUG TOXICITIES.

Chemical structure of a drug and its metabolites

Dose of the drug

Rates of toxic metabolite formation vs. detoxification

(Dependent on concentrations of enzymes and cofactors, which in turn are affected by genetics, gut microflora, diet, and other drugs as inducers, inhibitors, etc.)

Immune recognition of macromolecular adducts of a drug or its metabolites

Efficiency of macromolecular repair mechanisms

BOX 1.2 A LIST OF SUBSTRUCTURES FOUND IN DRUGS THAT HAVE BEEN MOST COMMONLY ASSOCIATED WITH THE FORMATION OF REACTIVE METABOLITES THAT HAVE CAUSED TOXICITIES.

Drugs that contain or can be metabolized to the following structures may cause toxic effects via the formation of reactive metabolites:

- Hydrazines and hydrazides
- Arylacetic or aryl-propionic acids
- Thiophene, furan, or pyrrole
- Anilines or anilides
- Quinone and quinone imines
- Medium chain fatty acids
- Halogenated hydrocarbons and some halogenated aromatics
- Nitroaromatics
- Moieties that can form reactive α,β -unsaturated enal-like structures
- Thiols, thiono compounds, and thiazolidinediones

The major chemical substructures found in drugs that have caused overt tissue injury in the past are listed in Box 1.2. For the most part, these structures are metabolized to reactive electrophiles that interact with tissue nucleophiles (primarily proteins) to form covalent adducts, a topic of considerable interest at present that is discussed in detail in the chapter titled *Covalent Drug–Protein Adducts: An Exploration of Their Role in Drug-Induced Liver and General Organ Toxicity*. In some cases, these electrophilic species can also lead to oxidation of tissue macromolecules, and in a few cases, radical metabolites can be formed that can react with oxygen to form toxic oxygen products (Fig. 1.1).

It is well known that there are a host of factors that influence not only the enzymes involved in the metabolism of drugs but also the disposition of these metabolites and their ultimate effect on our biological system. Genetics and gene regulation play a very significant role in the rates of reactive metabolite formation, in their disposition as described in the chapter on *Genetics of Drug Disposition*, and in the response of the cell/tissue/organism to the effects of the metabolites. The first work in the area of pharmacogenetics was published over 50 years ago [26], and now, genome-wide association studies are helping to define the role of particular genes involved in drug toxicities (for discussions, see Refs 27 and 28). The advancing field of toxicogenomics is discussed in the chapter titled *The Application of Preclinical Toxicogenomics for Predicting and Understanding Drug-Induced Toxicity and Metabolism*, and the influence of genetics and gene regulation on drug interactions and drug metabolism is the topic of the chapters titled *Clinical Implications of CYP Induction-Mediated Drug–Drug Interactions*, and *Regulation of Drug Metabolizing Enzymes and Transporters in Infection, Inflammation, and Cancer*. Additional work in proteomics and metabolomics/metabonomics is extending our understanding of the effects of drugs and

Figure 1.1 A simplified scheme for general mechanisms of drug metabolite-mediated drug toxicities.

drug metabolites at the cellular and whole body levels, thereby providing additional insights on phenotypic variations in drug metabolism, drug toxicities, and drug interactions. Proteomics in drug toxicities is the subject of the chapter titled *Proteomics in Drug Discovery and Development*, and metabolomics/metabonomics is the subject of the chapter titled *Metabonomics in Understanding Drug Metabolism and Toxicology*.

Finally, there are a host of other factors that can affect either the metabolism of drugs or the response of our biological system to the metabolites formed (Box 1.1). The dose of a drug (or any chemical substance) was recognized as a very important factor in as early as the 1500s when Paracelsus stated, “All substances are poisons; there is none which is not a poison. The right dose differentiates a poison from a remedy.” Thus, the lower the dose of a drug, the lower the amounts of toxic metabolites that can be generated. In most instances, this translates to a decreased risk for toxicity. However, many toxic effects of drugs occur in only a small percentage of individuals who take the drug. These idiosyncratic drug reactions are not yet very predictable, and several factors, such as inflammatory episodes, may leave an individual at more risk to an idiosyncratic drug reaction. This is the subject of the chapters titled *Idiosyncratic Drug Reactions* and *Animal Models of Idiosyncratic, Drug-Induced Liver Injury: Emphasis on the Inflammatory Stress Hypothesis*. Other factors such as drugs acting as inhibitors of drug metabolizing enzymes (see chapter titled *Drug–Drug Interactions 1: Inhibition*) age and diet (see chapters titled *Age-Dependent Expression of Human Drug-Metabolizing Enzymes* and *Phytochemical Modulators of Human Drug Metabolism: Drug Interactions with Fruits, Vegetables, and Botanical Dietary Supplements*) can also play a significant role in drug metabolism-related drug toxicities.

In summary, our knowledge of drug-mediated toxicities and the role that drug metabolites play in those toxicities has increased dramatically over the last 50 years. Advances in systems biology approaches to better define the most important factors in drug-metabolism-based toxicities should identify new biomarkers that can provide early signals of potential drug toxicities and lead to improvements in drug safety.

2.1 INTRODUCTION

Metabolism is a process that converts nonpolar, lipid-soluble substances to polar more water-soluble products that facilitates their excretion from the body, renally or via the biliary route. It is the body's major line of defense against potentially toxic xenobiotic substances, including drugs and environmental chemicals. Consequently, it is the major clearance mechanism for most drugs and reduces the total body burden of these compounds by transforming them into one or multiple products. Although the conversion of compounds can occur chemically, most metabolic reactions are catalyzed by an array of enzyme systems in the body. These reactions are typically categorized as phase 1 or functionalization and phase 2 or conjugative reaction types. In functionalization reactions, xenobiotics are metabolized via oxidative, reductive, and/or hydrolytic pathways, with P450-mediated oxidation reactions predominating [1,2]. Conjugative reactions, on the other hand, result in conversion of the substituents introduced during functionalization reactions, or those already present in the xenobiotic, by derivatization to polar metabolites such as glucuronide and sulfate conjugates.

Metabolism reactions generally result in detoxification of xenobiotics and are accompanied by the formation of chemically stable metabolites, which are devoid of pharmacological or toxicological activities. However, in some cases, these reactions can convert drugs to products that are either chemically reactive or pharmacologically active, a process that is commonly referred to as *metabolic activation* or *bioactivation*

Scheme 2.1 Bioactivation of drugs.

(Scheme 2.1) [2,3]. The chemically reactive metabolites that are formed may interact with cells in numerous ways, such as covalently binding to cellular constituents or by stimulating peroxidation and decomposition of cellular lipids. In contrast, pharmacologically active metabolites are chemically stable. These metabolites can influence the therapeutic effect of a drug (on-target activity) or they could have off-target activities unrelated to the action of the parent molecule. In some instances, they might even reverse the pharmacological action of the parent drug.

Most, if not all, functionalization and conjugation reactions can result in bioactivation. The production of an ultimate toxin or a pharmacologically active metabolites involves either a single enzymatic reaction or, in some cases, several enzymatic and/or chemical reactions. Even though all enzymes have the propensity to catalyze the metabolic activation of compounds, cytochrome P450 (P450) enzymes, which generally dominate metabolism, play a major role in the metabolic activation of drugs [4–10]. The primary focus of this treatise is to provide an overview of the bioactivation by P450 to pharmacologically active and chemically reactive metabolites.

2.2 BIOACTIVATION TO PHARMACOLOGICALLY ACTIVE METABOLITES

Compounds transforming into active metabolites fall into two classes. One category includes conversion of active parent molecules to active metabolic products [11–16]. Alternatively, a biologically inactive compound can also undergo enzymatic conversion to metabolites that are pharmacologically active. Prodrugs are compounds that fall in this category [17–21].

2.2.1 Active Metabolites Produced from Bioactivation of Pharmacologically Active Drugs

Approximately 20% of the drugs marketed in the United States have been shown to form active metabolites [11]. Several classes of drugs produce active metabolites via P450 catalysis. Although all P450-mediated reactions can convert drugs to active metabolites, hydroxylation of aliphatic, alicyclic, or aromatic rings and N- or O-dealkylation reactions commonly result in metabolites that are equipotent or more potent than parent compound. Other biotransformation reactions such as epoxidation of an unsaturated system or heteroatom oxidation can also form active metabolites. In addition to improved pharmacodynamics due to increased potency, the metabolite may sometimes possess improved pharmacokinetic properties such as a longer half-life, lower probability of drug–drug interactions (DDIs) and lesser variability. Alternatively, the metabolites may have improved overall safety profile and better solubility than the parent drug. Active metabolites possessing one or more of the above attributes have been developed and marketed as drugs. Discussed below are examples of P450-catalyzed transformation reactions that convert the parent drug to pharmacologically active metabolites, some of which have been introduced as commercial products.

2.2.1.1 Aromatic and Aliphatic Hydroxylation. Two classic examples where aromatic oxidation of drug molecules leads to activation are atorvastatin (Lipitor) and tamoxifen. Atorvastatin undergoes extensive CYP3A4-catalyzed metabolism in the liver to two active hydroxy metabolites, *ortho*-hydroxy-atorvastatin (*o*-OH-atorvastatin) and *para*-hydroxy-atorvastatin (*p*-OH-atorvastatin) (Fig. 2.1). Both metabolites have

Figure 2.1 CYP3A4-catalyzed conversion of atorvastatin to *para*- and *ortho*-hydroxy-atorvastatin.

potency that is similar to that of the parent drug *in vitro* and it is speculated that at least 70% or more of the HMG CoA reductase inhibitory activity of atorvastatin is attributed to these two metabolites [22].

Likewise, tamoxifen, an estrogen receptor antagonist, which is extensively used for endocrine treatment of breast cancer is primarily converted to two metabolites that contribute to the antiestrogenic activity of the parent drug. These metabolic transformations are the CYP2D6-mediated 4-hydroxytamoxifen, and a second-generation metabolite, *N*-desmethyl-4-hydroxytamoxifen (endoxifen) (Fig. 2.2). The latter is probably formed via CYP2D6-catalyzed aromatic hydroxylation of *N*-desmethyltamoxifen, which is a major circulating metabolite in humans. Although both metabolites are more potent than the parent drug in terms of binding affinity and in suppressing estrogen-dependent cell growth, endoxifen is said to be the main contributor to the therapeutic activity of tamoxifen in patients [23,24].

Pharmacological activation of flutamide, a potent antiandrogen used for the treatment of prostatic cancer, by CYP1A2 to 2-hydroxyflutamide is a good example of instances in which the oxidation of an aliphatic side chain results in the formation of an active metabolite (Fig. 2.3) [25]. After a 250 mg dose of flutamide, the plasma concentrations of 2-hydroxyflutamide are much higher than those of the parent drug and contribute to the efficacy [26].

Figure 2.2 Metabolism of tamoxifen to its active metabolites, hydroxytamoxifen and endoxifen.

Figure 2.3 Metabolism of flutamide to its active metabolite 2-hydroxyflutamide by CYP1A2.

Figure 2.4 Metabolism of bupropion to active metabolites, *R,R*-hydroxybupropion, *S,S*-hydroxybupropion (radafaxine), *threo*-hydrobupropion, and *erythro*-hydrobupropion.

Similarly, clinical data have indicated that the biological activity of bupropion, an atypical antidepressant and smoking cessation aid, has been attributed to its active metabolites, *R,R*-hydroxybupropion, (*S,S*)-hydroxybupropion (radafaxine), *threo*-hydrobupropion, and *erythro*-hydrobupropion [27–30] (Fig. 2.4). The pharmacological activity appears to be primarily due to radafaxine, as plasma levels of these metabolites greatly exceed those of the parent drug. Although the *threo*-hydrobupropion and *erythro*-bupropion are probably formed via reduction of the carbonyl group, the formation of (*R,R*)-hydroxybupropion and radafaxine is mediated by CYP2B6 via hydroxylation of the *t*-butyl group [31]. The hydroxyated metabolites are generally in equilibrium with their respective morphinol derivatives that are formed via intramolecular cyclization [29].

Some drugs (e.g., terfenadine and losartan) are bioactivated to pharmacologically active metabolites following multiple P450-catalyzed oxidations. Terfenadine, an antihistamine used for the treatment of allergic conditions is converted to the carboxylic acid metabolite fexofenadine in two steps (Fig. 2.5) [32,33]. The first step in the formation of fexofenadine involves hydroxylation of the methyl group which is subsequently converted to fexofenadine. Most antihistaminic activity of terfenadine is attributed to fexofenadine formation *in vivo* [34,35]. Terfenadine was shown to promote the inhibition of cardiac ion channels (potassium ion currents) leading to prolongation of the QTc interval and ventricular arrhythmia. This risk of cardiac arrhythmia led to the withdrawal of terfenadine in the late 1990s. Fexofenadine lacks this property and is devoid of antiarrhythmic side effects of terfenadine [36,37]. Additionally, fexofenadine causes less drowsiness than first-generation histamine-receptor antagonists as a result of its poor permeability across the blood–brain barrier because of its disposition by efflux transporters such as Pgp [38].

Losartan, the first selective angiotensin II (AT1-subtype) receptor antagonist to be used in the treatment of hypertension and congestive heart failure, is oxidized by CYP2C9 to an active carboxylic acid metabolite (Fig. 2.6) [39]. Its formation involves

Figure 2.5 Metabolism of terfenadine to fexofenadine by CYP3A4.

Figure 2.6 Metabolism of losartan and hydroxyzine to its carboxylic acid metabolites.

oxidation of the hydroxymethyl group to the corresponding aldehyde intermediate, which is consequently converted to the corresponding carboxylic acid metabolite (Fig. 2.6). This metabolite is a long-acting (6–8 h), noncompetitive antagonist at the AT₁ receptor and is 10–40 times more potent than the parent drug [40].

An example where the conversion of a hydroxymethyl group to an active carboxylic acid metabolite has resulted in commercialization of an active metabolite is that of cetirizine. Cetirizine (Zyrtec) is a second-generation antihistamine that is selective against H₁-receptor antagonist and is widely prescribed for seasonal and perennial allergic

rhinitis, and for dermatological conditions such as urticaria and pruritus. It is an acid metabolite of hydroxyzine (Atarax) and is formed via oxidation of the primary alcohol (Fig. 2.6). Approximately 45–60% of orally administered hydroxyzine undergoes oxidative metabolism to a carboxylic acid metabolite that possesses activity at H_1 histamine receptors and has a relatively small volume of distribution [41]. Although the enzymes for this biotransformation are not known, it can be speculated that this reaction is at least partially catalyzed by P450 enzymes. Not only does cetirizine have greater affinity for the H_1 receptor compared to hydroxyzine, but is also a long-acting nonsedating agent. This is partially attributed to its lack of distribution into brain tissue as a result of its strong Pgp substrate properties and poor membrane permeability [42].

2.2.1.2 Dealkylation Reactions. N/O-Dealkylation is one of the most common biotransformation reactions that can result in active metabolites. A classic example where O-dealkylated metabolite has replaced the parent drug in the market is that of acetaminophen. Acetaminophen is an active metabolite of phenacetin, which was once widely used as an analgesic (Fig. 2.7). Phenacetin was withdrawn because of its carcinogenic and kidney-damaging properties. Acetaminophen, on the other hand, is devoid of any carcinogenicity risks at therapeutic doses and quickly replaced phenacetin. It is currently one of the most popular analgesics in the market [43,44]. Likewise, desvenlafaxine (Pristiq), which was developed as a serotonin norepinephrine reuptake inhibitor (SNRIs) in the treatment of depression, is a major active O-dealkylated metabolite of venlafaxine (Effexor) (Fig. 2.7). The CYP2D6 catalyzed O-dealkylation leads to approximately 10-fold increase in potency at inhibiting serotonin uptake than norepinephrine uptake compared to venlafaxine [45]. Desvenlafaxine as a drug has several advantages over venlafaxine in that the former has a better safety and pharmacokinetic profile relative to the latter.

A P450-catalyzed O-dealkylation, which led to the development of a second-generation antihistaminic agent, is that of desloratadine (Clarinx). Desloratadine is an active metabolite of loratadine (Claritin) and approximately 10-fold more potent than loratadine [46]. Desloratadine is formed via CYP3A4-mediated oxidative decarbamylation of loratadine (Fig. 2.8) [47]. It is more potent and also has better pharmacokinetic properties such as lower oral clearance with greater systemic

Figure 2.7 O-Dealkylation of phenacetin and venlafaxine to their active metabolites, acetaminophen and desvenlafaxine.

Figure 2.8 Metabolism of loratadine to desloratadine.

Figure 2.9 CYP3A4-catalyzed metabolism of sunitinib to *N*-desethylsunitinib, an active metabolite.

concentrations at comparable oral doses and a longer plasma elimination half-life and shows less pharmacokinetic variability in comparison to loratadine [46]. Further desloratadine does not cause drowsiness because it does not readily enter the central nervous system. Owing to its superior pharmacokinetics and pharmacodynamic and safety profiles, the standard human dose is half as much as that of loratadine.

Active metabolites that have been either marketed as drugs, or have to be monitored *in vivo* as a result of N-dealkylation, are quite common. For instance, the CYP3A4-catalyzed N-dealkylated metabolite of sunitinib (Sutent) is equipotent and has a longer half-life than the parent drug (Fig. 2.9) [48–50].

Many psychotropic drugs are converted into active metabolites via the N-dealkylation pathway [51–53]. Benzodiazepines are one such class of psychoactive agents that undergo N-dealkylation or hydroxylation and usually yield pharmacologically active metabolites. The formation of active metabolites is one of the factors that have been actually used in their classification as long-acting or short-acting agents. Those compounds that are transformed into an active metabolite which has a long

elimination half-life are classified as long-acting agents. Examples of benzodiazepines that fall into this class are diazepam (Fig. 2.10) and flurazepam (Fig. 2.11). On the other hand, temazepam, oxazepam (both of which are active metabolites of diazepam), and lorazepam (Fig. 2.11) are classified as short-acting agents as extensive metabolism of these agents results in rapid elimination of the active principle.

Figure 2.10 Metabolism of various benzodiazepines to active metabolite, nordiazepam.

Figure 2.11 Structures of other benzodiazepines, flurazepam, temazepam, and lorazepam.

Chlordiazepoxide (Fig. 2.10) was the first benzodiazepine to be synthesized and marketed for clinical use as an antianxiety agent in the 1960s. The compound is extensively metabolized and most of its activity is attributed to nordiazepam, which is formed via a sequence of reactions (Fig. 2.10). Since nordiazepam has a long half-life due to very slow biotransformation, and it can potentially accumulate in the body after few days of treatment following repeated administration. Nordiazepam has also been detected as a major metabolite in the metabolism of other benzodiazepines including pinazepam, diazepam, medazepam, prazepam, and halazepam (Fig. 2.10). Hydroxylation of nordiazepam at position 3 yields another active metabolite oxazepam (Fig. 2.10), which has been marketed as a short-acting agent for the treatment of anxiety and insomnia and in the control of symptoms of alcohol withdrawal.

Like the benzodiazepines, several tricyclic antidepressants (TCAs) are also converted to active metabolites via N-dealkylation. Some of these demethylated metabolites have better pharmacokinetic properties and have been marketed as drugs in their own right. For example, amitriptyline and imipramine, used for the treatment of major depression in the United States, are primarily converted to its respective N-demethylated metabolites, nortriptyline and desipramine (Table 2.1), which have been marketed as second-generation antidepressant agents. The incidence of side effects in these second-generation antidepressants is lower than their predecessors. Table 2.1 also shows examples of other TCAs that are transformed to active metabolites via N-dealkylation.

Even though drug activation to a pharmacologically active metabolite is a minor pathway for some drugs, metabolism of the parent drug directly in the target organ can sometimes lead to pharmacological modulation at the site of action. For example, antianxiety agent alprazolam is metabolized to two hydroxylated metabolites by CYP3A enzymes, a major, 4-hydroxy alprazolam metabolite that is pharmacologically less active and a minor α -hydroxy alprazolam (α -OHALP) metabolite which is (pharmacologically more active) in humans (Fig. 2.12) [54–56]. It is speculated that the formation of large amounts of α -OHALP at the site of action potentially impacts the pharmacological activity of this antianxiety drug [57,58].

2.2.1.3 Other Reactions Leading to Active Metabolites. As mentioned previously, other P450 catalyzed can also result in conversion of drugs to active metabolites. For instance carbamazepine-10,11-epoxide, derived from carbamazepine, has anticonvulsant activity comparable with that of its progenitor (Fig. 2.13) [59]. Similarly, CYP2D6- and 2J2-catalyzed S-oxidation of the methylthio group in thioridazine yields two active metabolites, the sulfoxide, mesoridazine, and the sulfone, sulforidazine [60,61]. Mesoridazine is twice as active as the parent drug and as a result it was introduced into clinical use as antipsychotic agent (Fig. 2.13) [62].

Leflunomide (Arawa) represents another interesting example which involves P450-mediated reductive bioactivation to an active metabolite. This drug is marketed as an orally active disease-modifying anti-inflammatory agent for the treatment of advanced rheumatoid arthritis [63]. The principal biotransformation pathway of leflunomide in humans involves an N–O bond cleavage of its isoxazole ring leading to the formation of α -cyanoenol metabolite (A771726) which is the active entity (Fig. 2.14) [63,64]. *In vitro* studies have shown that this ring cleavage is catalyzed by CYP1A2 [65]. All activity of leflunomide is ascribed to this ring-opened metabolite which is found

circulating in humans since the circulating levels of the parent drug are below the limit of detection.

There are instances where the biotransformation could result in metabolites with activities that might even reverse the pharmacological action of the parent drug. For instance nefazodone is metabolized by humans into three pharmacologically active metabolites, hydroxynefazodone, triazolodione, and N-dealkylation of nefazodone to *m*-chloro phenylpiperazine (mCPP) by CYP3A4 (Fig. 2.15) [66–69]. Although, triazolodione and hydroxynefazodone may contribute significantly to the antidepressant effects of nefazodone, mCPP acts an agonist of 5-HT_{2c} receptor, an action which might be expected to produce an anxiogenic effect [70,71].

Similarly, the truncated phenolic metabolite of tamoxifen (metabolite E) formed by the cleavage of dimethylaminoethyl side chain (Fig. 2.16) is predominantly estrogenic

**Figure 2.12** Hydroxylation of alprazolam to its hydroxylated metabolites.

Figure 2.13 Metabolism of carbamazepine and thioridazine to its active metabolites.

Figure 2.14 Ring opening of the isoxazole ring of leflunomide to an active metabolite.

in its activity in contrast to tamoxifen and its two metabolites, hydroxytamoxifen and endoxifen (Fig. 2.2), which are antiestrogenic [72–74].

It is important to note that active metabolites which contribute to the efficacy can also elicit side effects that are observed after administration of the parent drug. For instance, mephenytoin is associated with increased incidence of serious toxic events including rash, agranulocytosis, aplastic anemia, and hepatitis [59]. Reports indicate that the *N*-desmethyl metabolite of *R*-mephenytoin (Methoin) (Fig. 2.17), which was once marketed under the name of nirvanol, is responsible for the bone marrow toxicity observed following mephenytoin administration [59]. Similarly serious adverse effects such as neurotoxicity and cardiotoxicity arising from meperidine (also referred to as *Demerol*) and propoxyphene (Fig. 2.17) are primarily attributable to their metabolites, normeperidine and norpropoxyphene, respectively [75]. Active metabolites themselves could induce or inhibit drug-metabolizing enzymes and as a result could also affect the pharmacokinetic profile of other drugs. For example, norfluoxetine, an active metabolite

Figure 2.15 Metabolism of nefazodone.

Figure 2.16 Structure of metabolite E of tamoxifen.

Figure 2.17 Structures of mephenytoin, meperidine, propoxyphene fluoxetine, and its N-demethylated metabolites.

of fluoxetine (Fig. 2.17) is a potent inhibitor of CYP2D6. As a result of the long half-life (up to two weeks) of norfluoxetine, the inhibitory effect persists for weeks after administration of fluoxetine [76]. This has led to the discontinuation of this drug.

2.2.2 Bioactivation of Inactive Compounds (Prodrugs)

As noted earlier, prodrugs are compounds with little or no pharmacological activity, which undergo biotransformation to a therapeutically active metabolite. Enzyme-mediated bioactivation of pharmacologically inactive compounds to active metabolites has been commonly used as a part of drug design when the drugs possess poor absorption properties or are unstable in the acidic pH of the GI tract following oral administration. Common reactions that usually catalyze this conversion are mediated by a broad class of hydrolytic enzymes, such as esterases, amidases, and phosphatases. However, P450-mediated oxidation reactions have also been employed to bioactivate molecules to moieties that can elicit their therapeutic action once formed *in vivo*. Some examples of where inactive compounds are activated via CYP-mediated biotransformation include encainide, cyclophosphamide, ticlopidine, and clopidogrel.

Encainide is a class IC antiarrhythmic agent. Indirect evidence has strongly suggested that the slowing of intracardiac conduction (prolongation of QRS) by encainide is mediated by its metabolites [77]. In humans, encainide is primarily metabolized to *O*-demethyl encainide and 3-methoxy-*O*-demethyl encainide. A third metabolite, *N*-demethyl encainide, also has been identified in serum from some patients [78]. Assessment of the activity of these metabolites revealed that *O*-demethyl encainide was nine times as potent as the parent drug and 3-methoxy-*O*-demethyl encainide equipotent to the parent drug. Some studies show that metabolic transformation of encainide to its *O*-demethyl derivative (Fig. 2.18) is a prerequisite for its antiarrhythmic activity as patients with reduced formation of this CYP2D6-catalyzed product show poor response to the drug [79,80]. Thus, in its own right, encainide is a prodrug of desmethylencaïnide that is activated by its CYP2D6-mediated *O*-demethylation. Similarly, some reports indicate that tamoxifen and leflunomide can also be classified as prodrugs because both these compounds are converted to metabolites that are

Figure 2.18 Metabolism of encainide to its active metabolites.

Figure 2.19 Bioactivation of cyclophosphamide by P450 and structure of ifosfamide.

even more potent than the parent and almost all the effects observed are due to these metabolites.

The oxazaphosphorines, cyclophosphamide and ifosfamide (Fig. 2.19), are alkylating agents that require bioactivation via P450 isoenzymes including CYP2C9 and 2B6 enzymes [81–83]. Cyclophosphamide has emerged as an important drug for the treatment of a wide variety of malignant diseases. The parent compound as such is inactive in the tissue culture. However, preincubation of the drug with liver homogenates activates the molecule suggesting that cyclophosphamide is a prodrug that requires oxidative metabolism to generate the active principle. The activation mechanism is depicted in Fig. 2.19. The initial step entails CYP-mediated oxidation of the ring on the carbon adjacent to the nitrogen of the phosphoramidate moiety. The hydroxylated metabolite is in equilibrium with the ring-opened aldehyde which undergoes spontaneous decomposition to the corresponding phosphoramidate mustard and acrolein. It is not clear if the phosphoramidate mustard or the parent nitrogen mustard (that is formed on hydrolysis, chemically or by phosphoramidase) is responsible for the therapeutic action [84,85].

Another interesting example which entails P450-mediated mechanism for activation to an active moiety is exemplified by drugs such as clopidogrel and ticlopidine (Fig. 2.20) [86]. These tetrahydrothienopyridine derivatives were developed as antithrombotic agents that inhibited platelet aggregation. Ticlopidine (Ticlid) was the first compound of this class, introduced to the market in 1979 for the prevention of thrombotic stroke. Clopidogrel (Plavix/Iscover) was later launched in the United States and Europe in the late 1990s for the reduction of atherosclerotic events in patients with

Figure 2.20 Metabolic activation of (a) clopidogrel and ticlopidine and (b) prasugrel.

stroke, myocardial infarction (MI), or peripheral arterial disease. Both ticlopidine and clopidogrel must be metabolized *in vivo* into a pharmacologically active derivative, in order to exert their activity as antagonists of the platelet ADP receptor P2Y (Fig. 2.20). Savi and coworkers [87] have demonstrated the importance of hepatic metabolism in eliciting clopidogrel's effect on platelet aggregation and that the active metabolite was formed through an intermediate, 2-oxo-clopidogrel. The metabolic activation occurs in two steps. The first step is a classical CYP2C19-catalyzed monooxygenation of the thiophene ring that leads to the thiolactone metabolites, 2-oxoticlopidine and 2-oxoclopidogrel. The second step involves sulfoxidation of the thiolactone, which undergoes spontaneous cleavage to the corresponding sulfenic acid intermediate. This highly reactive intermediate forms a covalent S–S bridge with a thiol group in platelet ADP receptors, thereby causing their long-lasting inactivation.

Prasugrel (Effient/Efient) (Fig. 2.20) is a newest member of this class of drugs [86]. Like ticlopidine and clopidogrel, it is extensively metabolized and also undergoes activation in the same way as clopidogrel and ticlopidine. The key difference between prasugrel and its predecessors, however, is the presence of the acetoxycarbonyl group at position 2 of the thiophene ring in prasugrel. Hence, the first step in the activation of prasugrel involves hCE2 ester hydrolysis to the thiolactone in contrast to the CYP-catalyzed oxidation to the thiolactone for clopidogrel or ticlopidine. The thiolactone is then activated to sulfenic acid via a CYP-mediated pathway that is similar to that described for clopidogrel and ticlopidine (Fig. 2.20).

2.2.3 Consequences of Formation of Pharmacologically Active Metabolites

Contribution of an active metabolite(s) to the overall pharmacological action of drugs depends on the disposition characteristics of the metabolites. Therefore, just the knowledge that a particular compound forms an active metabolite and has specific pharmacological properties is not sufficient. The free concentration of this metabolite should be sufficient enough at the target site to produce a significant effect. Further, most active metabolites have longer plasma elimination half-lives than parent drugs. This can lead to increased accumulation of the metabolites upon chronic dosing, even when they are formed as minor metabolites and their systemic concentrations upon acute dosing appear to be very low. Thus, if an active metabolite has significant potency and a good pharmacokinetic profile, and is formed in sufficient concentrations, it is very likely that there is a greater and/or longer duration of pharmacological action following administration of a parent drug. The result is a complex dose–response relationship, especially if the metabolite contributes significantly to the therapeutic effect of the drug and accumulates in tissues. This might necessitate dose adjustment. It is therefore necessary to identify active metabolites early on and monitor their plasma concentrations, in addition to the parent, in order to assess its concentration–response relationship and guide therapy [88,89].

Secondly, it is important to assess the factors affecting the formation of active metabolites. All factors that affect the metabolism of a principle drug will influence the formation of active metabolites. Some important factors include genetics, hepatic and renal impairment, and age. Additionally, other disease states, interactions with other drugs (inhibition or induction of enzymes) that can alter the levels of enzymes and therefore affect the amount of active metabolites formed. Among all these, genetic polymorphism can have a significant impact on efficacy/safety if active metabolites that are formed by polymorphic enzymes contribute to the therapeutic effect of the drug. For instance, codeine is primarily metabolized by CYP2D6 and undergoes O-demethylation to morphine. Owing to genetic variability in the CYP2D6 enzyme, patients receiving codeine can be poor, intermediate, or fast metabolizers of codeine into its active metabolite, morphine. Given the same dose, poor metabolizers may receive minimal relief, whereas fast metabolizers may experience a morphine overdose [75]. Likewise coadministration of codeine with quinidine a 2D6 inhibitor results in increased levels of the drug, lesser efficacy, and increased codeine-induced toxicity [90]. On a similar note, as CYP2D6 is the rate-limiting enzyme catalyzing the conversion of tamoxifen into metabolites with significantly greater affinity for the estrogen receptor and greater ability to inhibit cell proliferation, not all women benefit from tamoxifen treatment. Also, the side-effect profiles vary considerably from patient to patient. Thus, both genetic and environmental (drug-induced) factors that alter CYP2D6-enzyme activity directly affect the concentrations of the active tamoxifen metabolites and the outcomes of patients receiving adjuvant tamoxifen. An *a priori* knowledge of the pharmacogenetic variation in CYP2D6 enzyme activity may therefore be useful in individualizing the hormonal therapy of breast cancer [91]. Further, coadministration of tamoxifen with paroxetine, a CYP2D6 inhibitor, has been shown to alter the efficacy of tamoxifen because of the decrease in the plasma concentrations of 4-hydroxytamoxifen and endoxifen [92].

More recently, a lack of clopidogrel effect has been reported in some patients treated with this drug [93]. As mentioned earlier, the polymorphic enzyme CYP2C19 is the

primary enzyme responsible in the bioactivation of clopidogrel. Thus, compared to the wild-type individuals, CYP2C19 variant allele carriers exhibit a significantly lower capability to metabolize clopidogrel to its active metabolite and inhibit platelet activation. These patients are at a higher risk of adverse cardiovascular events. Investigations to understand this have demonstrated that genotyping of patients can readily predict this nonresponsiveness and poor inhibition of platelet activation. Consequently, the regulatory agencies have modified the prescribing information of this drug to highlight the impact of CYP2C19 polymorphism on efficacy. Other examples where genetic variation can impact the therapeutic efficacy of a drug include losartan and cycloguanil [11]. Overall, these examples emphasize the potential importance of pharmacogenetic considerations in the assessment of active metabolites in the development of drugs.

2.3 BIOACTIVATION CHEMICALLY REACTIVE METABOLITES

The concept of metabolic conversion of chemicals to reactive products that covalently bind critical protein components stems back to the pioneering work by Miller and coworkers who demonstrated the carcinogenic and hepatotoxic activity of polycyclic aromatic hydrocarbons and aminoazo dyes to arise from their P450-mediated bioactivation [94–96]. Since then several reviews on bioactivation of drugs to chemically reactive intermediates have appeared in the past few decades [5–8,97–99]. A brief overview of P450-mediated reactions that result in chemically reactive intermediates and examples of drugs that undergo bioactivation via these mechanisms is described here.

All major isoforms of P450 can catalyze metabolic activation of drugs to reactive intermediates [4–6,98,100]. Many organic functional groups are particularly susceptible toward P450-mediated bioactivation to reactive intermediates. Details on these functional groups and their proposed bioactivation pathways catalyzed by P450 enzymes have been recently reviewed [101]. Although all oxidation reactions are capable of generating a reactive metabolite, some of the common reactions by which the P450 transform drugs to reactive metabolites are described below.

2.3.1 *N*-Oxidation of Aromatic Amines

A compound containing an aniline group is generally associated with serious adverse side effects such as hypersensitivity reactions, lupus, and carcinogenesis [102]. Most of these side effects are attributed to P450-catalyzed metabolic activation of the primary amine via *N*-oxygenation to hydroxylamine derivative. The resulting *N*-hydroxylamine products are acylated to produce highly reactive ester derivatives such as the *N*-acetoxy, *N*-sulfonyloxy, or *N*-phosphatyl esters, which can undergo heterocyclic cleavage to yield reactive aryl nitrenium ion species that covalently bind to DNA (Fig. 2.21) [103]. Several arylamines including 2-amino-3-methylimidazo[4,5-*f*]quinoline (IQ), 2-amino-3,5-dimethylimidazo[4,5-*f*]quinoline (MeIQ), or 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine (PhIP) bind to DNA to form adducts via the nitrenium ion. An alternative mechanism has also been proposed in which the hydroxylamine is oxidized to the electrophilic nitroso derivative, that can covalently bind to macromolecules via reaction with sulfhydryl groups yielding the corresponding

Figure 2.21 Metabolic activation of arylamines by P450 via the reactive ester pathway.

sulfonamide adducts (Fig. 2.22) [104,105]. This mode of bioactivation has been demonstrated for several very popular drugs such as sulfamethoxazole, dapsone, and procainamide (Fig. 2.22) [106–109].

Like arylamines, most drugs containing a nitroaromatic ring also generate a nitroso intermediate. However, the process of bioactivation of nitroaromatics to the nitroso intermediate involves a two-electron reduction as opposed to N-oxidation and is a part of the six-electron reduction to the aniline moiety (Fig. 2.23). Chloramphenicol is a good example where the nitro group is reduced to form a reactive intermediate [110]. Other examples containing a nitro group include nimesulide, dantrolene, and nilutamide (Fig. 2.23). The toxicity of all these compounds is ascribed to the reduction of the nitro group [111]. P450 and/or CYP-reductase is the primary enzyme that catalyzes this bioreduction of the nitro group. However, other enzymes including xanthine oxidase, aldehyde oxidase, and quinone reductase can also play a role [111].

2.3.2 Epoxidation of Arenes and Olefins

P450-catalyzed epoxide formation is an important metabolic transformation of drugs and xenobiotics containing an aromatic or an olefin moiety. Most often, the resulting arene or olefin oxides undergo detoxification via spontaneous rearrangement or subsequent epoxide hydrolase-mediated hydrolysis to the more stable arenols or dihydrodiols. However, in some instances, epoxide intermediates can react with nucleophilic biomolecules (e.g., DNA or proteins) to form macromolecular adducts that can manifest carcinogenicity or hepatotoxicity [5].

Bioactivation of polycyclic aromatic hydrocarbons such as benzo[*a*]pyrenes is a good example where arene oxides have been implicated in carcinogenesis [112]. Numerous metabolic intermediates of benzo[*a*]pyrene have been postulated to be chemically reactive and capable of binding to nucleic acids. However, the key metabolite that efficiently

Figure 2.22 Metabolic activation of sulfamethoxazole via the nitroso intermediate.

Figure 2.23 Bioactivation of compounds containing nitroaromatic rings.

Figure 2.24 Metabolic activation of compounds via the arene oxide pathway.

alkylates nucleic acids is 7,8-dihydroxy-9,10-oxy-7,8,9,10-tetrahydrobenzo[*a*]pyrene (Fig. 2.24). The first step involves the oxidation of benzo[*a*]pyrene to 7,8-dihydroxy-7,8-dihydrobenzo[*a*]pyrene by P450 and epoxide hydrolase. Subsequent stereoselective epoxidation of the 9,10-double bond of this diol yields *R*9, *R*10 and *S*9, *S*10-epoxides [113]. Both these epimers are highly reactive and react with nucleic acids to form a covalent adduct between the C-2 amino group of guanosine and the C-10 position of the hydrocarbon [114,115]. Similarly, arene oxides have been implicated in cytotoxic and tetratogenic effects that are manifested by phenytoin and thalidomide [116,117] (Fig. 2.24).

The formation of an epoxide intermediate is also a common pathway in the bioactivation of heteroaromatic rings [118]. For example, the chloro-imidazopyridine ring in alpidem is subject to P450 bioactivation, thus leading to the formation of a reactive epoxide that reacts with GSH to yield sulfhydryl-linked conjugates, which have been detected in humans (Fig. 2.24) [119]. Similarly, epoxidation also plays role in the hepatotoxicity of five-membered heteroaromatic rings. For example, the first step in the bioactivation of furan derivatives involves a P450-catalyzed oxidation to a heteroarene oxide. This can directly react as hypothesized in the case of furosemide (Fig. 2.25) [120], or most often it undergoes spontaneous ring opening to the enedialdehyde that reacts with sulfhydryl groups in proteins (Fig. 2.26) [121]. Oxidative ring opening

Figure 2.25 Metabolic activation of heteroaromatic rings by epoxidation.

Figure 2.26 Ring opening of furan rings.

of furan and irreversible protein binding of the corresponding substituted ϵ -ketoenals has also been reported during metabolism studies with the lipooxygenase inhibitor L-739,010 and an experimental anti-HIV drug, L-754,394 (Fig. 2.26) [122,123].

The toxicity of thiazole rings is also attributed to their P450-catalyzed oxidative ring scission to the corresponding thioamide metabolites (Fig. 2.27) [124]. This is exemplified by studies on metabolism and toxicity of thiabendazole, a compound that is widely used as an agricultural fungicide and an anthelmintic [125]. As shown in Fig. 2.27, thiabendazole is oxidatively metabolized to thioformamide and the benzimidazol-2-ylglyoxal metabolites in preclinical species and humans. Although the initial step is epoxidation of the thiazole moiety, it subsequently undergoes ring scission to the corresponding thioformamide, which is believed to be the proximate toxicant of the compound. Likewise, the clinical hepatotoxic effects of sudoxicam

Figure 2.27 Bioactivation of compounds containing a thiazole ring.

have been circumstantially linked to the bioactivation of its thiazole ring to reactive thioureido and thiourea metabolites [126].

The situation is more complex in the case of thiophene compounds, as these compounds form the thiophene epoxides and thiophene-*S*-oxides upon oxidative metabolism [118,127]. Earlier studies by Bray and coworkers [128] provided evidence that thiophene-2,3-epoxide is the obligatory intermediate leading to glutathione adducts. Likewise, the formation of an epoxide in the bioactivation tienilic acid has not been ruled out [129]. More recently, a glutathione adduct of 2-hydroxy-2,3-dihydrothienopyridine which is formed via attack of the glutathione molecule on the epoxide intermediate has been detected and characterized (Fig. 2.28) [130]. In rare cases, the thiophene epoxides have been shown to undergo a ring opening to enedialdehydes as reactive intermediates as demonstrated in the bioactivation of suprofen [131].

Several reports have provided evidence that formation of a thiophene-*S*-oxide intermediate is the primary activation pathway in the oxidative metabolism of thiophene compounds [132–136]. Some drugs that undergo bioactivation via this pathway include tienilic acid, methapyrilene, or zileuton (Fig. 2.29) [134,136–138]. Other heteroaromatic rings containing a sulfur atom in the ring also undergo metabolic activation via the *S*-oxide intermediate in addition to epoxidation. For instance, incubation of L-766,112, a potent and selective inhibitor of human COX-2, with rat and rhesus monkey hepatic microsomal fractions under oxidative conditions generates the electrophilic thiazole-*S*-oxide metabolite (Fig. 2.30) [139]. The corresponding *S*-oxide has been trapped with GSH to give the GSH conjugate. A similar reaction has also been observed with compounds containing a thiazole ring as exemplified in the metabolism of the nonpeptidyl thrombopoietin receptor agonist [140].

Like the arenes, the alkene containing compounds are bioactivated to their corresponding alkene oxide intermediates [98,141–143]. Olefin bioactivation via an epoxide

**Figure 2.28** Bioactivation of thiophene derivatives.**Figure 2.29** Metabolic activation of thiophenes to thiophene-S-oxides.**Figure 2.30** Metabolic activation of L-766,112 by P450.

Figure 2.31 Metabolic activation of aflatoxin and structure of norethindrone.

intermediate is well illustrated by metabolism studies of aflatoxin (Fig. 2.31) [144]. A CYP3A4-catalyzed epoxidation of the 2,3-double bond in aflatoxin B1 results in a very reactive epoxide intermediate which binds to RNA rendering the compound extremely toxic. Similarly, the hepatic side effects observed following administration of the contraceptive agent norethindrone have been attributed to the formation of 4,5-epoxide metabolite [145–147].

2.3.3 Two-Electron Oxidation of Electron Rich Compounds

Many drugs containing a nitrogen, oxygen, or carbon atoms ortho or para to one another in an aromatic ring are susceptible to a two-electron oxidation that yields quinone imine, quinones, or quinone methide intermediates. These intermediates are quite reactive (depending on the substituents on the aromatic ring) and the reactivity is ascribed to the presence of α,β -unsaturated carbonyl or imine moieties, that can react with biologically important nucleophiles via a 1,4-Michael addition reaction [148–153].

2.3.3.1 Quinone Imines. Prime examples of drugs undergoing metabolic activation to quinone imines are acetaminophen and amodiaquine. Acetaminophen contains a *para*-hydroxyacetanilide core, which undergoes a CYP3A4-catalyzed two-electron oxidation to form the quinoneimine N-acetyl *para*-benzoquinone imine (NAPQI) species that can form covalent adducts to protein (Fig. 2.32) [154–157]. Similarly, amodiaquine, an antimalarial agent, which is effective against chloroquine resistant isolates of *Plasmodium falciparum* undergoes metabolic activation of the 4-hydroxyphenylamino moiety in the molecule to the corresponding quinone imine and arylates sulfhydryl nucleophiles in a macromolecule (Fig. 2.32) [158–160]. Metabolism studies of amscarine, an antileukemic agent, in rats have also led to the detection of glutathione conjugates as the main biliary metabolite (Fig. 2.32) [161]. Amascarine contains a *para*-aminosulfonamide moiety that is oxidatively transformed to a quinone dimine intermediate which is analogous to a quinone imine observed in the case of amodiaquine (Fig. 2.32) [162]. This reacts with the sulfhydryl group of glutathione resulting in GSH adducts observed in the rats or with other sulfhydryl-containing biological molecules.

Quinone imine intermediates are also observed in drugs that are hydroxylated on the aromatic ring containing a “masked aniline.” For instance, nonsteroidal

Figure 2.32 P450-catalyzed oxidation of aminophenol derivatives to quinone imines.

anti-inflammatory drugs, diclofenac and lumiracoxib, undergo a CYP3A4- and 2C9-catalyzed aromatic hydroxylation, respectively, to the corresponding aminophenol derivative (Fig. 2.32) [163,164]. These metabolites are known to undergo further P450- or myeloperoxidase (MPO)-catalyzed two-electron oxidation to the corresponding electrophilic quinone imine intermediates, and this event is thought to contribute to the hepatotoxicity associated with these two drugs [165,166].

Other drugs that are postulated to elicit their toxicity by their transformation to the corresponding hydroxyphenyl metabolites and subsequent oxidation to the quinone

Figure 2.33 Metabolic activation of nefazadone, trazadone, erlotinib, and gefitinib.

imine intermediate are nefazadone, trazadone, and erlotinib (Fig. 2.33) [167–169]. Generally, halogen atoms are added to aromatic rings in order to block the positions that are prone to hydroxylation. However, in rare instances, these halogenated analogs can undergo oxidative dehalogenation by P450 to yield aminophenol derivatives that are further bioactivated to the quinone imines. For instance, gefitinib, an inhibitor of the epidermal growth factor receptor (EGFR) tyrosine kinase, is bioactivated to a quinone imine via oxidative defluorination followed by oxidation of the corresponding hydroxyaniline metabolite (Fig. 2.33) [170].

Nitroaromatic compounds can also undergo bioactivation to quinone imines. However, this process involves two pathways. The first step is the six-electron reduction of

Figure 2.34 Metabolic activation of tolcapone.

the nitro group to the corresponding amine. The corresponding aromatic amine is then oxidized to an *ortho*-quinone imine intermediate either by peroxidases or P450. An example involving CYP-catalyzed bioactivation of a compound containing a nitroaromatic ring is depicted in studies on metabolism of tolcapone (Fig. 2.34) [171].

2.3.3.2 Quinones. Quinones are toxicophores that are produced via a two-electron oxidation of phenolic compounds [148,149,172]. Like the quinone imines, these intermediates are Michael acceptors, which generally react with sulfhydryl nucleophiles on a macromolecule. Interestingly, the presence of an electron rich sulfhydryl group can make the reoxidation of the corresponding hydroquinone back to the quinone intermediate. This in turn can covalently bind with second sulfhydryl-containing residue in the macromolecule and therefore lead to cross-linking of the macromolecule. Because of this, the initial nucleophilic attack of protein-SH to quinones does not generally represent a true detoxication reaction [173,174]. Examples of drugs that bioactivated to the quinones by P450 are raloxifene and ethinylestradiol. Raloxifene is a selective estrogen receptor modulator (SERM), which is effective in the treatment of osteoporosis in postmenopausal women. Glutathione adducts of raloxifene were identified in incubations with human liver microsomes that were supplemented by NADPH and GSH [175]. These adducts are postulated to derive by nucleophilic attack of GSH on the extended quinone intermediate, which is then trapped by GSH conjugation (Fig. 2.35). Likewise, the 2-hydroxyethinylestradiol metabolite formed by P450-catalyzed oxidation of the oral contraceptive, ethinylestradiol, is converted to the corresponding *ortho*-quinone intermediate by P450 (Fig. 2.35) [176].

2.3.3.3 Quinone Methide. Quinone methides differ structurally from quinones, in that one of the carbonyl oxygen atoms is replaced by a methylene or substituted methylene group. These reactive metabolites are generally formed following the oxidation of 4-alkylphenol moiety which may be present in a drug itself or one that is formed following hydroxylation of aromatic rings in a drug. Like all reactive intermediates, the selectivity of a quinone methide depends on its rate of formation as well as its reactivity. The presence of a carbon instead of an oxygen or nitrogen atom in a quinone methide makes this intermediate much more reactive than its analogs (quinone or the

Figure 2.35 Oxidation of phenolic derivatives to quinones.

Figure 2.36 Bioactivation of troglitazone.

quinoneimine) with a reduced capacity for redox cycling. Therefore, quinone methides generally react in biological systems via nonenzymatic Michael additions. Most SERMs that undergo conversion to extended quinones are also bioactivated to quinone methides [177]. Troglitazone, the first glitazone used for the treatment of type II diabetes mellitus and withdrawn from the market for liver toxicity, also forms the quinone methide via oxidation of the substituted chromane ring system (Fig. 2.36) [178]. However, an alternative mechanism, which involves a novel oxidative cleavage of the thiazolidine-dione ring, potentially generating highly electrophilic *R*-ketoisocyanate and sulfenic acid intermediate, has also been proposed in the bioactivation of troglitazone [178]. Both the bioactivation processes are CYP3A4 mediated as incubations in the presence of ketoconazole inhibits the formation of the GSH conjugates.

2.3.3.4 Imino Methide. Imino methides are analogous to quinone methides in that a nitrogen atom replaces an oxygen atom. Generally, compounds containing a 3-methylindole motif are bioactivated to imino methides. A prime example for this class is that of 3-methylindole. This is a potent pneumotoxicant, found in tobacco smoke and intestinal or ruminant contents. Reports indicate that its toxic effects are a result of bioactivation via P450-mediated two-electron oxidation to an iminomethide (Fig. 2.37) [179–181]. Some compounds that are bioactivated via this pathway include zafirlukast and L-745,870 (Fig. 2.37) [182,183]. Trimethoprim, a bacteriostatic antibiotic, which is mainly used in the prophylaxis and treatment of urinary tract infections, also undergoes bioactivation to an imino methide intermediate that is formed by P450 or peroxidase-catalyzed oxidation of the diaminopyrimidine moiety (Fig. 2.37) [184].

Figure 2.37 Formation imino methide intermediates via bioactivation of 3-alkylindoles and trimethoprim.

2.3.3.5 Iminium Ions. Cyclic tertiary amines can undergo a two-electron oxidation to form iminium ions as intermediates that can serve as electrophilic centers for reactions with macromolecules [185]. As a part of the detoxification pathway, these intermediary iminium ions are often oxidized to the biologically less active lactams in a reaction that is catalyzed by the liver cytosolic enzyme aldehyde oxidase (Fig. 2.38) [186]. The most generally accepted catalytic pathway for this reaction assumes an initial single electron transfer (SET) step from the amine substrate nitrogen lone pair to generate an aminyl radical cation which, following loss of a proton, is converted to a highly reactive carbon-centered radical (Fig. 2.38). A second single-electron oxidation of the carbon-centered radical gives, in the case of the P450-catalyzed reaction, the carbinolamine, which is in equilibrium with the iminium ion product [185]. The same reaction is catalyzed by monoamine oxidase (MAO). However, the electron acceptor in the case of CYP450 is the perferryl oxo species (Fe(V)O) species, while the electron acceptor for the MAO-catalyzed reaction is the oxidized flavin moiety (FAD) [185]. A variety of cyclic tertiary amines undergo P450-catalyzed oxidative metabolism to form chemically reactive iminium metabolites. Phencyclidine undergoes α -carbon oxidation

Figure 2.38 Bioactivation of cyclic amines to iminium ion intermediates.

Figure 2.39 Metabolic activation and a ring contraction of a piperazine ring via an iminium intermediate.

to form the chemically reactive iminium intermediate, a pathway which is associated with covalent binding to macromolecules (Fig. 2.38) [187,188]. A similar bioactivation of the tobacco alkaloid (*S*)-nicotine to an iminium ion intermediate (Fig. 2.38) that forms covalent bonds to biomacromolecules has been reported [189].

The pyrrolizidine alkaloids (PAs) constitute a large class of natural products many of which are carcinogenic, genotoxic, neurotoxic, and hepatotoxic [190]. This toxicity is attributed to their conversion to pyrrolyl metabolites via the P450-mediated α -carbon oxidation pathway (Fig. 2.38) [185,191,192].

Doss and coworkers in metabolism studies of a selective melanocortin receptor subtype-4 agonist have demonstrated a novel metabolic activation and a ring contraction of a piperazine ring via an iminium intermediate. The transformation is a consequence of a nucleophilic attack of a GSH molecule on the iminium ion intermediate (Fig. 2.39) [193].

Another interesting case of a P450-catalyzed bioactivation sequence involving an iminium ion as a reactive intermediate has been documented with 6,7-dimethyl-2,4-di-1-pyrrolidinyl-7*H*-pyrrolo[2,3-*d*]pyrimidine (U-89843) (Fig. 2.40) [194]. U-89843 is a novel antioxidant with prophylactic activity in animal models of lung inflammation whose clinical development was suspended because of its genotoxicity. Incubation of [14 C]-U-89843 with liver microsomes resulted in NADPH-dependent covalent binding of radioactive material to microsomal protein. Characterization of the corresponding methanol, GSH, and *N*-acetylcysteinyl adducts of U-89843 in NADPH-supplemented rat liver microsomes supported a bioactivation pathway involving the formation of a resonance-stabilized iminium intermediate formed via dehydration of the alcohol metabolite, in a manner similar to that observed with 3-methylindole. The highly reactive iminium species is suspected to react with nucleophilic sites within proteins resulting in adducts.

2.3.4 Mechanism-Based Inactivators

Generally, P450s that bioactivate compounds are often targets for modification by reactive intermediates that are generated from them. This can lead to irreversible binding of a molecule to the enzyme and eventually inactivation of the enzyme. The compounds that fall into this category are often referred to as “*mechanism-based*,” “*suicide*,” “*time-dependent*,” or “*catalysis-dependent*” inactivators. Two types of

Figure 2.40 Bioactivation of U-89843.

mechanism-based P450 inactivators can result from the bioactivation of compounds, namely, quasi-irreversible and irreversible inhibitors. In the case of quasi-irreversible inhibitors, these reactive intermediates coordinate with the heme prosthetic group leading to the formation of a catalytically inactive metabolite–inhibitor (MI) complex of the P450 enzyme(s). Alternatively, reactive intermediates generated from the metabolism of irreversible inactivators can covalently react with an active site amino acid residue(s) within the apoprotein following their bioactivation and/or cause direct alkylation/arylation of the heme prosthetic group resulting in heme destruction [195–199]. Whether the reactive metabolite formed by a P450 enzyme can covalently bind to the enzyme that generates it depends in part on the reactivity and longevity of the intermediate itself. Additionally, the proximity of amino acid residues in the active site of P450 to the electrophile also influences the potential of a compound to act as an inactivator. If the metabolite is “very reactive” it may not be able to diffuse out of the active site of the enzyme into cell milieu where it can react with cellular constituents and/or reduced glutathione. Instead, it may alkylate the heme moiety, which can lead to heme destruction. Alternatively, the intermediate formed can covalently bind with a nucleophilic amino acid residue within the apoprotein, which is in the vicinity of the active site where the intermediate was formed. In general, heme alkylation invariably inactivates P450, whereas amino acid alkylation may result in loss of catalytic activity.

2.3.4.1 Quasi-Irreversible Inactivation. This type of time-dependent inactivation of P450 is common and involves a metabolite inhibitor complexation (MI complex). Once the compound is metabolized, the initial products of oxidation can tightly coordinate with the P450-Fe(II) enzyme resulting in the formation of MI complex and renders the enzyme inactive. The MI complex exhibits an absorbance maximum in the Soret region between 448 and 456 nm when the heme iron is in the Fe(II) state [200]. Aliphatic or aromatic amines are a class of compounds that can cause enzyme inhibition via this mode of bioactivation [195]. A primary amine is generally required for a compound to

Figure 2.41 Structures of quasi-irreversible inhibitors.

cause a quasi-irreversible inhibition [201,202]. Some noteworthy examples that have shown to undergo MI complexes include amine-based calcium channel blockers that are widely used for the treatment of hypertension, angina pectoris, and other cardiovascular diseases [203]. For instance, 1,4-dihydropyridines such as nicardipine, verapamil, and diltiazem have been classified as quasi-irreversible inhibitors of CYP3A4 (Fig. 2.41). Excluding nicardipine, both verapamil and diltiazem undergo N-demethylation to the corresponding primary or secondary amines which can complex with Fe(II) [204–206]. The irreversible mechanism-based inactivation of P450 3A4 by the estrogen receptor antagonist, tamoxifen and its N-demethylated metabolite is also accompanied by MI complex formation with the ferrous form of the enzyme [207]. Several members of the macrolide class of antibacterial agents that contain a tertiary amine group are also known to form MI complexes with P450–Fe(II) following their metabolism to the nitroso intermediate. For instance, troleandomycin, erythromycin, and clarithromycin can mediate its CYP3A4 inhibitory effects by converting to nitrosoalkanes and the consequent formation of inactive MI complexes of P450 (Fig. 2.41) [105]. The reactive species is believed to be a nitrosoalkane obtained by enzymatic oxidation of the amine through the intermediate hydroxylamine metabolite. Although the primary amine is

Figure 2.42 Bioactivation of 1,3-benzodioxole groups.

the required moiety for binding, secondary and tertiary amines have also been shown to inactivate the enzyme and can serve as suitable precursors for MI complexation provided they are N-dealkylated to primary amines.

Compounds that contain the methylenedioxyphenyl or 1,3-benzodioxole motif also inactivate P450 enzymes via MI complex formation with the enzyme following bioactivation [208–210]. The phosphodiesterase-5 inhibitor tadalafil and the selective serotonin reuptake inhibitor paroxetine are examples of drugs that contain the 1,3-benzodioxole group that form MI complexes with human P450 3A4 and P450 2D6, respectively, resulting in the mechanism-based inactivation of these enzymes (Fig. 2.42) [211,212]. Although speculative, the evidence points toward a reactive carbene intermediate obtained by hydrogen atom abstraction from the methylene carbon or by the elimination of water from a hydroxymethylene intermediate. An alternate pathway to inactivation of P450 by methylenedioxy group involves metabolism of the dioxole moiety to an *ortho*-quinone via a catechol, which can react with amino residues in the enzyme as exemplified by methylenedioxymethamphetamine (ecstasy) and safrole (Fig. 2.42) [213,214].

2.3.4.2 Mechanism-Based Inactivation of P450s by Covalent Modification. Most functionalities that are bioactivated (described above) and lead to macromolecular adduct formation have the potential to covalently modify the enzyme active site and therefore inactivate it. Hence, it is not surprising that most of the compounds that possess these functionalities are inactivators of P450. For example, the extended quinone formed via bioactivation of raloxifene is responsible in inactivation of CYP3A4 [215]. More recently, Baer and coworkers [216] have demonstrated that a single equivalent of raloxifene is bound to the cysteine residue in the P450 apoprotein. Previous reports have also shown that 3-alkylindoles, that are bioactivated via imino methide intermediates, are potential suicide inactivators of CYP enzymes [182,217–220]. However, more

Figure 2.43 Bioactivation and mechanism-based inactivation by a 2-methyl substituted indole derivative.

recently, a report showing bioactivation of 2-methyl-substituted indole (Fig. 2.43), which is a potent dual inhibitor of chemoattractant receptor-homologous molecule expressed on T-helper type-2 cells and D-prostanoid receptor, has been published [221]. During evaluation as a potential treatment for asthma and allergic rhinitis, 2MI was identified as a mechanism-based inactivator of CYP3A4 *in vitro* as well. The NADPH-dependent increase in 2MI covalent binding to a 55- to 60-kDa microsomal protein was consistent with irreversible binding to CYP3A4.

Several compounds containing a furan moiety are inactivators of CYP enzymes. Because of extensive mechanistic and Structure activity relationship (SAR) studies with furan analogs, it has been proposed that P450-mediated furan ring scission to reactive intermediates (discussed above) leads to mechanism-based inactivation of P450. Evidence for P450 inactivation by reactive intermediate(s) derived from furan ring scission has also been presented for the experimental HIV protease inhibitor L-745,394 that inactivates P450s [222]. An interesting example of a furan containing compound where metabolism of the furan moiety is not involved in the inactivation is that of furafylline (Fig. 2.44). This compound is a mechanism-based inactivator of CYP1A2. Several studies have been conducted to understand the mechanism of inactivation of

Figure 2.44 Bioactivation and mechanism-based inactivation of CYP1A2 by furafylline.

this compound. SAR and deuterium-isotope studies indicate that inactivation arises via bioactivation involving the methyl group attached to the C-8 carbon of the xanthine nucleus and no metabolism of furan ring to reactive intermediates is discernible [223,224]. Metabolism studies using H_2^{18}O indicate that the inactivation occurs as a result of P450 1A2-catalyzed two-electron oxidation of the 8-methylxanthine to the corresponding imidazomethide intermediate that is covalently bound to the enzyme.

As described above, thiophene containing compounds are bioactivated to thiophene-*S*-oxides and formation of these intermediates have been implicated as the rate-limiting step in the etiology of adverse drug reactions. In addition, these *S*-oxide intermediates can also inactivate 450s as exemplified by studies on metabolism of clopidogrel and ticlopidine. Both these compounds are potent suicide inactivators of CYP2C19 and 2B6 [225–228]. Similarly, *S*-oxidation of the thiophene ring in tienilic acid results in inactivation of CYP2C9 that forms it [229]. The anti-inflammatory agent suprofen also inactivates CYP2C9 and like tienilic acid, oxidation of the thiophene ring in the molecule is implicated in its inactivation process [131].

Drugs containing alkenes or alkynes (especially a terminal alkyne) as a functional group have been associated with mechanism-based inactivation of P450 enzymes [230–234]. Two mechanisms for the inactivation process have been described with alkynes (Fig. 2.45). The first mechanism involves initial oxidation of the triple bond on the terminal carbon followed by a 1,2-hydrogen shift of the terminal hydrogen to the vicinal carbon that is thought to generate the reactive ketene intermediate. This intermediate can have two possible fates: it is hydrolyzed to the carboxylic acid product or it can acylate the apoprotein [234,235]. An alternative mechanism involves the formation of oxirene (especially with internal alkynes), which then leads to heme- or apoprotein alkylation [234]. Some examples of alkyne-containing compounds that are potent mechanism-based inactivators of P450s are 17α -ethinylestradiol and mifepristone (Fig. 2.45) [236,237]. Both are inactivators of CYP3A4. Ethinylestradiol inactivates the enzyme via metabolism of the terminal acetylenic moiety to a reactive ketene intermediate that leads to heme- and apoprotein alkylation. On the other hand, mifepristone has an internal alkyne that alkylates the apoprotein but not the heme prosthetic group.

Hydrazine or hydrazide group containing drugs are also commonly associated with inactivation of major CYP enzymes. For instance, the antihypertensive drug, dihydralazine or the antituberculosis drug, isoniazid displays mechanism-based inactivation of human P450 isoforms (Fig. 2.46) [238,239]. Inactivation by dihydralazine is ascribed to the formation of a free carbon radical via the diazene, which results in alkylation of the heme. Consistent with these findings, P450 1A2 autoantibodies have been found

Figure 2.45 Mechanism-based inactivation by alkynes.

in the serum of patients suffering from dihydralazine-mediated hepatitis, suggesting a key role for P450 in the overall toxicological process. A nonselective mechanism-based inactivation of multiple mammalian P450 enzymes by the hydrazine analog 1-aminobenzotriazole (ABT) proceeds via alkylation of the heme prosthetic group as demonstrated by the characterization of an N,N' -bridged phenylene-protoporphyrin IX adduct from livers of rats treated with ABT [240,241]. The proposed mechanism, which accounts for the formation of the phenylene-protoporphyrin IX, involves the putative formation of the electrophilic benzyne intermediate via initial oxidation of the primary amine functionality in ABT (Fig. 2.46).

A number of other functionalities have been implicated in mechanism-based inactivation of CYP enzymes, including halogenated compounds (chloramphenicol), dihydropyridines, dihydroquinolines, various organosulfur compounds, including thiols, thioamides, dithiocarbamates and isothiocyanates, and cyclopropylamines. The mechanism of inactivation and examples of drugs containing these functionalities has been extensively reviewed [195,198,199,242].

2.3.5 Consequence of Bioactivation of Drugs to Reactive Metabolites

Circumstantial evidence suggests that bioactivation of relatively inert functional groups to reactive metabolites may contribute toward certain drug-induced adverse reactions. Adverse drug reactions pose a significant health problem as they contribute to patient morbidity and mortality and commonly compromise good patient care and represent one of the most common causes for pharmaceutical product recalls and black box warning labels. Life-threatening idiosyncratic adverse drug reactions that are usually unpredictable and rare such as hepatotoxicity, severe cutaneous reactions, anaphylaxis, and blood dyscrasias are a major cause of drug withdrawal after the drug has

Figure 2.46 Structures of hydrazines derivatives and mechanism-based inactivation by aminobenzotriazole ABT.

been launched. Mechanism-based inactivation, on the other hand, can translate into clinical DDIs. Some of these can be potentially deleterious, and can also lead to withdrawal of the perpetrator drug. Inactivation of enzymes has a greater potential to lead to DDIs when compared to reversible inhibition. This is because a CYP modified by a mechanism-based inactivator is irreversibly modified and has to be replaced by newly synthesized enzyme in order for activity to be regained. Several pharmaceutical companies have therefore implemented definitive screens to address the bioactivation potential of new drug candidates. Mechanism-based inactivation of major human CYP enzymes by new compounds is also routinely assessed in a drug-discovery paradigm. In an event that the new candidate shows a potential to form a reactive intermediate or exhibits time-dependent inhibition of a CYP, an attempt to replace the offending group is made.

Like in the case of formation of active metabolites, genetic polymorphism in addition to other factors can significantly affect the formation of reactive metabolites and protein adducts, leading to altered drug toxicity [243–246]. It can also result in differential inactivation of P450s. Information on whether common genetic polymorphisms affect P450 inactivation and may thereby affect the frequency of DDIs is therefore required. Additionally, drug-associated factors, kinetics of drug–protein adduct formation and degradation, affected proteins and organs, and genetic and pathological conditions of the patients are also important factors that need to be considered to when managing the risks related to adduct formation as a result of bioactivation to reactive metabolites. The potential for DDI and/or ensuing immune-mediated toxicity of a new drug candidate due to bioactivation also depends on the overall disposition (extent of metabolism leading to P450 inactivation relative to latent metabolic or nonmetabolic fate), daily dose, therapeutic regimen (acute vs chronic), and the intended target population.

Despite the risks associated due to covalent binding to enzymes, mechanism-based inactivators have also been used to our advantage and exploited to provide therapeutic benefits. For instance, the coformulation of ritonavir, a potent inhibitor of CYP3A4, with lopinavir, a novel protease inhibitor with relatively low bioavailability, has been shown to significantly improve the pharmacokinetic properties and hence the activity

of lopinavir against HIV-1 protease [247]. Mechanism-based inactivators have also been used as powerful molecular probes for delineating the catalytic specificities of particular P450s and for obtaining important information regarding P450 structure and function.

2.4 SUMMARY

This chapter summarizes the bioactivation of drugs by P450. Even though all enzymes can catalyze metabolic activation of compounds, P450 enzymes, which generally dominate metabolism, play a major role in the metabolic activation of drugs. Bioactivation by P450 enzymes can result in pharmacologically active metabolites that can influence the overall pharmacological response of the drug. Although the major advantage of the formation of active metabolites is the prolonged pharmacological effect of the drug, it is important to note that it results in a complex dose–response relationship that results in the monitoring of the parent drug as well as all its metabolites and necessitates the adjustment of the dose of the drug. Alternatively, metabolic activation of drugs can result in reactive intermediates that have the propensity to covalently bind with the nucleophilic centers in biomolecules and elicit drug-induced toxicities and DDIs depending on the target protein. Overall, bioactivation of compounds clearly has its advantages and disadvantages. It is therefore important to evaluate the potential of metabolic activation of a candidate drug early on in discovery and development so that it can allow one to mitigate the risks associated with it.

3.1 INTRODUCTION

The potential for drug-induced adverse reactions with new drug candidates entering clinical trials is a principal concern for the drug development industry, due largely to the unfortunate frequency of untoward outcomes reported and/or black-box warnings associated with many drugs [1]. In addition, postmarketing incidences of hepatotoxicity and other severe adverse events have been noted with a number of otherwise useful medications, such as troglitazone (withdrawn in 2000), and most recently, lumbiracoxib (withdrawn in 2008). These increasingly observed outcomes have prompted the FDA to draft a guidance on the topic of drug-induced liver injury (<http://www.fda.gov/downloads/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/UCM174090.pdf>), which accounts for up to 50% of liver failure [2]. The debate is ongoing about the ultimate cause of adverse drug reactions (ADRs), and, in particular, idiosyncratic adverse drug reactions (IADRs), which currently cannot be predicted in preclinical animal models. One prevailing hypothesis is that reactive electrophilic metabolites generated by metabolic activation (e.g., bioactivation) may covalently modify critical biomacromolecules such as protein and DNA. These modifications of protein lead to “haptization” and the potential for an autoimmune response and/or various organ toxicities [3]. Considering that the majority of drug molecules are metabolized to some degree by the cytochrome P450 enzyme system, which are predominantly expressed in the liver, their purported role in the bioactivation

of drug molecules is not unexpected. In fact, in recent years, a multitude of reports and reviews describing *in vitro* evidence of reactive metabolite formation via cytochrome P450-mediated metabolism and the functional groups (e.g., structural alerts) that are particularly prone to bioactivation have been published [4,5]. As a result, *in vitro* assays with human liver fractions such as microsomes, where new chemical entities are incubated in the presence of various nucleophilic trapping agents (e.g., glutathione (GSH), cyanide, methoxylamine), are commonplace within drug metabolism departments in pharmaceutical industries as a strategy to identify the potential risk of reactive metabolite formation [6,7].

While the cytochrome P450 enzymes are generally the primary focus of drug metabolism scientists, there are many other drug-metabolizing enzymes that may contribute to the biotransformation of xenobiotics that are perhaps underappreciated, particularly when considering generation of reactive metabolites in extrahepatic target tissues. Non-cytochrome P450 drug-metabolizing enzymes such as flavin-containing monooxygenase (FMO), monoamine oxidase (MAO), alcohol dehydrogenase (ADH), and peroxidases such as prostaglandin H synthase (PGHS) and myeloperoxidase (MPO), have all been reported to contribute to the metabolism of xenobiotics [8,9]. Thus, their potential role in bioactivation of drug molecules also deserves increased attention.

The focus of this chapter is on specific examples of non-P450 drug-metabolizing enzymes and the potential role they may play in bioactivation and toxicity of xenobiotics. Table 3.1 highlights the enzymes discussed in this chapter, including the predominant tissues in which they are expressed and subcellular location. It is the hope of the authors that this compilation of selected examples will lead to an increased knowledge and awareness regarding reactive metabolite formation by metabolic enzymes outside the cytochrome P450 family.

3.2 FLAVIN-CONTAINING MONOOXYGENASES (FMO)

FMOs are a family of microsomal enzymes involved in the oxidation of nitrogen-, sulfur-, phosphorous-, selenium-, and other nucleophilic heteroatom-containing small molecules. Although these enzymes share a similar subcellular location, substrate overlap, coenzyme, and a common role in xenobiotic detoxification with cytochrome P450 enzymes, FMOs are distinct in a number of ways. The rates of xenobiotic turnover by FMOs are generally two to three times higher than that of P450 enzymes [10]. Additionally, the pH optimum for FMO-catalyzed transformations is 9–10. These enzymes also display a thermal instability in the absence of NADPH [11]. These three characteristics have often been exploited in determining the role of FMO in xenobiotic metabolism.

In humans, there are five functional FMO enzymes (FMO1–FMO5) as well as six pseudogenes. Human FMO1 (expressed in kidney) and FMO3 (expressed in liver) appear to play a dominant role in xenobiotic metabolism, while the role of FMO2, FMO4, and FMO5 in xenobiotic metabolism is currently not well established [12]. FMO isoforms have different substrate selectivity, and have distinct age-, gender-, species-, and tissue-dependent expression. This must be kept in mind when comparing FMO-mediated metabolism in different species because the expression of FMOs may differ [13]. The major steps in the mechanism of FMO-mediated oxidation are presented in Fig. 3.1. Typically, products from this mechanism include *N*-oxides and sulfoxide

TABLE 3.1 Expression and Subcellular Localization of the Non-P450 Metabolic Enzymes Described within this Chapter

Enzyme (Isoform)		Tissue(s)	Subcellular Fraction
Flavin-containing monooxygenase (FMO)	FMO1	Kidney	Microsomes
	FMO3	Liver	Microsomes
	FMO5	Liver	Microsomes
Monoamine oxidase (MAO)		Liver	Mitochondria
		Brain	
		GI tract	
		Placenta	
		Heart	
		Blood vessels	
		Kidney	
		Platelets	
Semicarbazide-sensitive amine oxidase (SSAO)		Blood vessels	Membrane-bound
		Plasma	
Alcohol dehydrogenase (ADH)	ADH1	Liver	Cytosol
	ADH2	Liver	Cytosol
	ADH3	Liver	Cytosol
	ADH4	GI tract	Cytosol
		Liver	
Prostaglandin H synthase (PGHS)		Kidney medulla	Microsomes Nuclei
		Platelets	
		GI tract	
		Brain	
		Lung	
		Bladder	
Myeloperoxidase (MPO)		Blood	Leukocytes
Aldo-ketoreductase (AKR)		Liver	Cytosol
		Brain	
NAD(P)H dehydrogenase [quinone] 1 (NQO1)		Stomach	Cytosol
		Kidney	
		Lung	
		Liver	
		GI tract	
NADPH cytochrome P450 reductase (CPR)		Liver	Microsomes
Aldehyde oxidase (AO)		Liver	Cytosol
Xanthine oxidase/xanthine dehydrogenase (XO/XD)		Liver	Cytosol

metabolites that are generally nonreactive, but a few examples exist where a reactive species is generated, which are discussed.

3.2.1 Thiocarbonyls

The conversion of thiocarbonyl compounds to reactive species by FMO enzymes is mechanistically well understood with several examples of compounds showing toxicity resulting from this bioactivation pathway. Thiourea, phenylthiourea, α -naphthylthiourea, ethionamide, thioacetamide, and thiobenzamide (Fig. 3.2) are a few examples

Figure 3.1 Catalytic cycle of FMO.

of thiocarbonyl compounds which have been shown to cause toxic outcomes [14,15]. The most common toxicity associated with thiocarbonyl compounds is pneumotoxicity and hepatotoxicity in rats. Additionally, the tuberculosis drug ethionamide has been associated with hepatotoxicity and dermal hypersensitivity in humans [16].

A generic example of the mechanism of bioactivation of a thiocarbonyl compound is depicted in Fig. 3.2. This bioactivation pathway proceeds via initial oxidation of sulfur generating a thioamide *S*-oxide. Further oxidation of the thioamide *S*-oxide results in formation of the reactive *S*, *S*-dioxide. Tautomerization of the *S*, *S*-dioxide to the iminosulfinic acid generates what is thought to be the reactive species, reported to react with nucleophiles as an acylating species giving rise to covalently modified proteins and lipids [16]. This observation may provide some mechanistic connection between the proposed bioactivation pathways by FMO and toxic outcomes that have been observed with thiocarbonyl-containing compounds, particularly within the lung [14].

3.2.2 Aryl Piperazines

Compared to the thiocarbonyls, less data has been presented to associate any toxicity of aryl piperazine-containing molecules with a particular biotransformation pathway and reactive metabolite. Despite these shortcomings, the examples presented in this section will provide additional instances of FMO-mediated bioactivation of substrates to reactive metabolite(s).

Rodriguez *et al.* have proposed that reactive metabolites of ketoconazole produced by an FMO-mediated pathway are a possible explanation for the observed hepatotoxicity [17]. Studies using rat hepatocytes with ketoconazole and its primary metabolite, *N*-deacetylketoconazole, indicate greater hepatotoxicity for the metabolite than for the

Figure 3.2 Examples of thiocarbonyl-containing compounds and bioactivation mechanism catalyzed by FMO.

parent drug. Additional reports have also shown that binding of radiolabeled ketoconazole or its metabolites to microsomal proteins is abrogated by heat inactivation of FMO in microsomes. Mechanistically, FMO-mediated metabolism of the secondary nitrogen of *N*-deacetyl ketoconazole results in the formation of the secondary hydroxylamine metabolite [18] as shown in Fig. 3.3. Further oxidation of this intermediate has been proposed to result in production of the potentially reactive nitron and/or aldehyde metabolites, although direct evidence supporting the formation or reactivity of these intermediates has not yet been presented.

Figure 3.3 Bioactivation of *N*-aryl piperazine moiety by FMO.

Work by Kalgutkar *et al.* involving 5-HT_{2c} agonists has likewise uncovered formation of reactive metabolites associated with the *N*-aryl piperazine moiety [19]. During safety evaluation, exposure of *Salmonella* cells with **1** (shown in Fig. 3.3) in the presence of S9 and NADPH resulted in a dose-dependent increase in reverse mutations. Additionally, incubation of [¹⁴C]-**1** with S9 fortified with NADPH resulted in a concentration-dependent increase in covalent binding of radioactivity to calf thymus DNA. Further examination of the metabolism of **1** in the presence of the trapping agents, GSH, cyanide, or methoxylamine was also undertaken. In addition to a GSH adduct and two methoxylamine trapped metabolites, an α -cyano hydroxylamine metabolite was also observed (Fig. 3.3), indicating the formation of an initial secondary hydroxylamine followed by a reactive nitron intermediate. While the involvement of FMO in the bioactivation of **1** has not been confirmed, the observed and proposed metabolites of **1** are strikingly similar to those of *N*-deacetylketonazole, which suggests that a rat FMO-mediated bioactivation pathway may be involved. Interestingly, in subsequent work with analog **2** in which the 3-chlorobenzyloxy moiety has been removed, no metabolism-dependent mutagenicity was observed [20] despite the finding of both a methoxylamine and cyanide conjugate. The authors propose that differences in the extent or nature of the metabolism of **2** compared to **1** explain the lack of mutagenicity of this compound.

3.2.2.1 4-Fluoro-*N*-Methylanilines. Numerous examples of hydroxylation of anilines or aniline containing structures at the para position have been shown to result in the formation of electrophilic quinoneimine species, which may be reactive with protein nucleophiles resulting in toxicity. A rational approach to mitigating the formation of this reactive species would be to substitute a fluorine atom para to the aniline nitrogen, decreasing the electron density of the aromatic ring and potentially blocking para hydroxylation. Despite attempts to block metabolic activation in this manner, several examples of oxidative dehalogenation resulting in the formation of *para*-hydroxyanilines have been documented. For most of these examples, a reaction mechanism involving cytochrome P450 has been invoked [21]. Interestingly, in addition to the involvement of cytochromes P450, FMO enzymes have also been shown to be proficient at catalyzing this bioactivation pathway.

A thorough characterization of 4-fluoro-*N*-methylaniline metabolism *in vitro* and *in vivo* was undertaken by Boersma *et al.* Formation of the oxidatively defluorinated metabolite, *N*-methyl-4-hydroxyaniline, was identified and its formation reported to be catalyzed by purified rat FMO [22]. Subsequent work demonstrated that recombinant human FMO1 (rFMO1) was also capable of generating this metabolite [23], with a mechanism involving electrophilic aromatic substitution being invoked to explain the product formation (Fig. 3.4). Delocalization of the aniline lone pair would direct the carbon at the para position to attack the distal oxygen of the peroxyflavin of FMO. The resulting tetrahedral intermediate could then eliminate HF to generate a reactive quinoneimine. Subsequent two-electron reduction would generate the final phenolic product. Coincubation of *N*-acetylcysteine (NAC) with 4-fluoro-*N*-methylaniline, rFMO1, and NADPH resulted in the formation of two NAC conjugates. This, along with the observation that the phenolic oxygen atom originates from molecular oxygen, provided evidence in support of the proposed mechanism. Not only does this example demonstrate a novel FMO-mediated biotransformation pathway, but it also highlights

Figure 3.4 Bioactivation of 4-fluoro-*N*-methylaniline by FMO to a reactive quinoneimine intermediate.

an FMO-mediated bioactivation pathway that, until this report, was essentially reserved for the cytochrome P450 enzymes.

3.3 AMINE OXIDASES

3.3.1 Monoamine Oxidase (MAO)

The MAO enzymes are integral membrane proteins localized in the mitochondrial outer membrane of most cell types and are dependent upon the cofactor flavin-adenine dinucleotide (FAD). These amine oxidases typically catalyze the deamination of endogenous primary biogenic amines such as dopamine (DA), norepinephrine, serotonin, and tyramine, and are widely distributed throughout the body, particularly the liver, brain, heart, blood vessels, and kidney [24,25]. The expression of MAO in the brain has made this a popular pharmacological target in the treatment of depression and Parkinson's disease [26]. However, side effects such as hypertensive crisis due to the inhibition of metabolism of tyramine (e.g., "cheese-effect") have lead to reduced interest in this therapeutic approach. MAO exists in two different forms, MAO-A and MAO-B (encoded by distinct genes; ~70% sequence similarity), and can be differentiated by substrate and inhibitor specificities. For example, MAO-A preferentially oxidizes serotonin and norepinephrine, and is selectively inhibited by clorgyline, whereas MAO-B oxidizes phenethylamine and benzylamine, and is inhibited by low concentrations of (*R*)-deprenyl [27]. Despite the predominant role of MAO in oxidizing endogenous amines, it is also involved in oxidizing a number of exogenous primary, secondary, and tertiary amines such as the triptan antimigraine drug sumatriptan [28], and the selective serotonin reuptake inhibitor (SSRI) antidepressant citalopram [29]. The observation of increased xenobiotic metabolism by MAO suggests that more emphasis should be placed on characterizing non-P450-mediated metabolism, particularly for amine-containing drug molecules.

MAO distinguishes itself from cytochrome P450 enzymes in multiple ways, including its subcellular location, which is the mitochondria. Interestingly, however, it has been demonstrated that liver microsomes, when prepared from frozen tissue, may contain MAO activity, as mitochondrial membranes apparently may end up included in the microsomal fraction as a contaminant [30]. The catalytic mechanism of MAO may be broken down into two main reactions: oxidative deamination and cofactor recycling. Steps a–e in Fig. 3.5 represent the "deamination" reaction, while step f represents the FAD-recycling step. MAO incorporates oxygen from water into the substrate to yield an aldehyde and an amine, and upon reoxidation of FADH₂ with molecular oxygen (O₂), produces hydrogen peroxide (H₂O₂) as a by-product. Figure 3.5 depicts the detailed catalytic mechanism by which MAO operates, including an example of MAO metabolism of a cyclic tertiary amine to a ring-opened aldehyde. Alternatively, the iminium intermediate may be oxidized by an enzyme called *aldehyde oxidase* (AO) to form the nonreactive lactam.

3.3.1.1 Tetrahydropyridines. The finding that prompted specific interest in MAO as it relates to bioactivation was the observation that MAO-B metabolically converts 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) into a potent neurotoxin (1-methyl-4-phenylpyridinium, MPP⁺) that can destroy dopaminergic neurons, leading to Parkinson-like symptoms in humans [31–33]. The Parkinson-like motor deficits

Figure 3.5 Catalytic mechanism of MAO.

were initially observed in drug addicts after self-administration of 1-methyl-4-phenyl-4-propionoxypiperidine (MPPP), an analog of meperidine that was contaminated with MPTP. MPTP undergoes oxidation to the iminium species 1-methyl-4-phenyl-2,3-dihydropyridinium (MPDP⁺) by MAO-B. However, instead of undergoing hydrolysis to produce the corresponding aldehyde and amine, is further oxidized to the neurotoxic MPP⁺ species within the brain (Fig. 3.6), which in turn is actively transported into dopaminergic nerve terminals by the DA uptake transport system [34] where it accumulates and interferes with mitochondrial respiration. Solid evidence supporting the role of MAO-B in this pathway was gathered when selective MAO-B inhibitors were shown to protect against MPTP neurotoxicity in mice and primates [35,36]. Also interesting is that while the iminium MPDP⁺ may be converted to the nontoxic lactam product by AO in tissues such as liver, this alternate detoxifying pathway is apparently not present in the brain, resulting in the accumulation of MPP⁺ and subsequent neurotoxicity [37]. Thus, the MPTP story represents a classic example of bioactivation by a non-P450 enzyme, followed by a perfect storm of events, where the lack of a detoxifying pathway in a specific tissue (e.g., brain) and a transport mechanism leads to a localized neurotoxic event in the nigrostriatum.

3.3.1.2 Dopamine. DA is a critical endogenous neurotransmitter in the brain with numerous physiological functions. It undergoes catabolism via multiple pathways, including MAO to form 3,4-dihydroxyphenylacetaldehyde (DOPAL). DOPAL may

Figure 3.6 Bioactivation of MPTP by MAO-B in brain.

Figure 3.7 Bioactivation of dopamine to a reactive aldehyde by MAO.

then undergo further catabolism to 3,4-dihydroxyphenylacetic acid (DOPAC) via aldehyde dehydrogenase (ALDH) (Fig. 3.7). Despite the critical physiological role that DA plays, it has been implicated as a neurotoxin, with a potential role in Parkinson's disease pathogenesis. However, several publications have pointed to the DOPAL metabolite of DA (generated by MAO) as the actual toxin [38,39]. For example, when both DOPAL and DA were directly injected into rat substantia nigra, DOPAL was toxic to DA neurons in a dose-dependent manner, with tissue necrosis observed at the highest dose, whereas DA itself showed no evidence of neurotoxicity at much higher doses [38]. Additional evidence for the role of DOPAL in neurotoxicity was elegantly demonstrated by showing that the lipid peroxidation products, 4-hydroxynonenal (4HNE), and malondialdehyde (MDA), inhibit further oxidation of DOPAL by the ALDH pathway, resulting in the accumulation of DOPAL and a subsequent increase in protein

modification [40,41]. These data have provided a unique mechanistic link between oxidative stress/lipid peroxidation and degeneration of DA neurons by a reactive aldehyde metabolite generated by MAO. Lastly, it has also been reported that 3,4-dihydroxyphenylglycoaldehyde (DOPEGAL), the MAO metabolite of norepinephrine, display neuronal selective toxicity [39], suggesting that bioactivation of endogenous molecules may be more common than expected. All of these findings confirm what was hypothesized over 50 years ago, which was that aldehyde metabolites of amines would be directly toxic to cells where they are formed [42].

3.3.2 Semicarbazide-Sensitive Amine Oxidase (SSAO)

Semicarbazide-sensitive amine oxidase (SSAO) oxidatively deaminates primary amines such as methylamine and benzylamine [43]. The name of this amine oxidase is derived from the fact that semicarbazide covalently interacts with and inhibits enzyme activity. SSAO is expressed in most mammalian tissues, and exists both as tissue-bound, as well as a soluble form in plasma [44]. The main tissue-bound form is in blood vessel smooth muscle layers, including cardiac tissue.

3.3.2.1 Allylamine. Allylamine is an aliphatic amine that was discovered to cause cardiovascular toxicity (e.g., lesions) in experimental animals [45]. Specifically, when rats were dosed with allylamine, myocardial necrosis and fibrosis resulted, which interestingly, resemble atherosclerotic disease [46]. However, when allylamine was codosed with semicarbazide, the severity of disease was dramatically reduced, which lead to the hypothesis that allylamine may be converted to acrolein by tissue-specific amine oxidases such as SSAO. In fact, the production of acrolein was confirmed in homogenates of rat aorta and heart [45]. Bioactivation of allylamine by SSAO to acrolein, a highly reactive aldehyde, is shown in Fig. 3.8. Providing a link between preclinical species and humans regarding the toxicity of acrolein, one human fatality following ingestion of allyl alcohol has been reported [47]. High concentrations of acrolein ($\sim 128 \mu\text{M}$)

Figure 3.8 Metabolic pathways and formation of the toxic aldehyde metabolite acrolein.

were found in the blood of this individual upon autopsy, and it was concluded that the cause of death was cardiotoxicity caused by acrolein. Interestingly, formation of acrolein in this case is likely catalyzed by another non-cytochrome P450 metabolic enzyme, namely, ADH, which is further discussed in the next section.

3.4 ALCOHOL DEHYDROGENASE

ADH is a member of the medium-chain dehydrogenase/reductase (MDR) superfamily. Other members of the MDR superfamily include quinonereductases and leukotriene B4 dehydrogenase [48]. These enzymes exist as dimers folded into two domains. Each monomeric subunit contains two zinc atoms, one structural and one catalytic, with the catalytic zinc anchored between the two domains. There are five classes of human ADHs designated ADH1–ADH5. Three isozymes of the ADH1 family exist, specifically ADH1A, ADH1B, and ADH1C [49]. Generally, all human isoforms are expressed in the liver, except ADH5, which was only identified at the gene and mRNA level. Additionally, the expression of ADH4 is higher in extrahepatic tissues, specifically the gastrointestinal tract [49].

ADH is involved in the NAD(H)-catalyzed oxidative metabolism of primary and secondary alcohols to aldehydes and ketones, respectively. Additionally, ADH may also catalyze the reduction of aldehydes back to alcohols producing NADH [50]. The general sequence of events in the mechanism of ADH-catalyzed oxidations is as follows [51,52]: (i) NAD^+ binding, (ii) alcohol binding via coordination to the catalytic zinc, (iii) deprotonation of the alcohol generating a zinc-bound alkoxide ion, (iv) hydride transfer from the alkoxide ion to NAD^+ thereby producing a zinc-bound aldehyde or ketone, (v) product release, and (vi) dissociation of NADH. The products of ADH-catalyzed reactions are aldehydes or ketones. Of these two species, aldehydes have been shown to be involved in reactions with macromolecules such as DNA and/or proteins. Despite known detoxifying enzymatic pathways for aldehydes, several examples exist for ADH-mediated bioactivation of molecules resulting in toxic outcomes.

3.4.1 Allyl Alcohol

Allyl alcohol is a widely used industrial chemical and synthetic intermediate. Extensive periportal necrosis has been observed in rats following administration of allyl alcohol [53]. Subsequent studies have shown that allyl alcohol is converted to the well-known toxic substance acrolein, which is present in tobacco smoke and fried foods, and is the toxic metabolite of the cancer drug cyclophosphamide. The metabolic bioactivation of allyl alcohol occurs in rat liver and lung S9 and cytosol, and this biotransformation is NAD^+ -dependent. Neither NADPH- nor NADP^+ -fortified incubations result in conversion of allyl alcohol to acrolein [54]. Additionally, this conversion is significantly inhibited by pyrazole [55]. Together these pieces of evidence support the involvement of ADH in the metabolism of allyl alcohol to acrolein (Fig. 3.8). Upon formation of acrolein, several possible pathways have been proposed which could explain covalent binding of acrolein to DNA or protein, subsequently resulting in potential toxicity. Michael addition of sulfhydryl groups occurs rapidly, resulting in a protective mechanism, such as in the case of GSH, or alkylated proteins, which may cause toxicity. Similarly, the imidazole of histidine has also been shown to be involved

in Michael addition to acrolein [56]. Formation of propenediamines with the nitrogen of lysine is another mechanism of protein adduction which has been shown to occur more slowly than that of Michael addition of sulfhydryls [53]. Uchida *et al.* have also identified an acrolein-lysine adduct, *N*^ε-(3-formyl-3,4-dehydropiperidino)lysine (FDP-lysine), formed by the reaction of lysine with two molecules of acrolein [56].

As shown in Fig. 3.8, there are also several other metabolic pathways that may be protective or may lead to other reactive species. Acrolein is converted by ALDH to acrylic acid which, despite being an α,β -unsaturated acid, is less reactive than acrolein. Addition of an ALDH inhibitor results in greater toxicity in animals administered acrolein, which suggests that this is a protective pathway [53]. In addition, two cytochrome P450-catalyzed pathways result in conversion of allyl alcohol to glycidol and acrolein to glycidaldehyde. Adding complexity to the nature of the toxicity is the fact that glycidaldehyde has been identified as both a mutagen and a carcinogen [53]. Both glycidol and glycidaldehyde are then hydrated to form the benign metabolites glycerol and glyceraldehyde, respectively. This example represents one of the more complex bioactivation pathways known, with multiple drug-metabolizing enzymes playing a role in either generation of reactive metabolite, or as protective mechanisms.

3.4.2 Felbamate

Felbamate (2-phenyl-1,3-propanediol dicarbamate) was approved in 1993 as an antiepileptic drug. In its first year on the market, felbamate was administered to ~120,000 patients [57]. A total of 34 cases of aplastic anemia resulting in 13 deaths and 23 cases of hepatic failure resulting in 5 deaths have been reported [58–60]. Studies of the *in vivo* metabolism of ¹⁴C-felbamate in rat, rabbit, dog, and human have resulted in the identification of two mono-hydroxylated metabolites (*p*-OHF and 2-OHF), a monocarbamate (MCF), and the carbamoyl propionic acid (CPPA) (Fig. 3.9). Of particular interest was the fact that CPPA was the major human

Figure 3.9 Bioactivation mechanism of felbamate to 2-phenylpropenal.

metabolite at ~12%, and the only other species in which this metabolite was observed was the dog [61]. On the basis of the observation of CPPA and the likely intermediacy of an aldehyde carbamate metabolite, the MacDonald group at the University of Virginia hypothesized that once formed, the aldehyde carbamate may undergo β -elimination to give 2-phenylpropenal as the reactive electrophile responsible for the observed toxicities of felbamate [62].

To support the hypothesis of toxicity mediated by 2-phenylpropenal, 2-phenylpropenal and its proposed precursor, the carbamoyl aldehyde, were synthetically prepared. Toxicity of these two compounds, as well as felbamate, MCF, CPPA, and two known toxic compounds, acrolein and 4-HNE was tested in a cytotoxicity assay. In this assay, 2-phenylpropenal showed similar toxicity to acrolein and 4-HNE, although the aldehyde carbamate was shown to be 10–100 times less potent, while MCF and CPPA were not toxic [61]. Additional studies of the reaction of GSH with 2-phenylpropenal in phosphate buffer indicated that the reaction was fast, with an observed half-life of ~40 s [63].

With data to support toxicity and reactivity of a likely intermediate in the metabolism of felbamate, attention turned toward the mechanism and rate of conversion of the aldehyde carbamate to 2-phenylpropenal. These studies showed the aldehyde carbamate to be chemically reactive, generating the expected 2-phenylpropenal and a cyclized oxazolidine product. Under phosphate buffered conditions at physiological pH, formation of the oxazolidine was favored but longer incubation times resulted in 2-phenylpropenal [61]. The observation of the oxazolidine species also leads to the proposal that this species acts as a latent form of 2-hydroxypropenal, able to escape the site of formation and travel to sites distal from the liver, where it may exert its effects [62].

The aforementioned metabolic conversions of felbamate to both nontoxic and toxic metabolites are demonstrated in Fig. 3.9. The bioactivation pathway leading to the aplastic anemia and hepatotoxicity observed for felbamate involves several non-P450-mediated biotransformations. Initially, one of the carbamate functionalities of felbamate is cleaved via an esterase, amidase, or hydrolase to give MCF, although neither the exact enzyme nor its subcellular location is known [64]. Oxidation of the primary alcohol to the aldehyde carbamate occurs via an NAD^+ -catalyzed ADH-mediated reaction. The aldehyde carbamate and the oxazolidine species are in equilibrium with decomposition of the aldehyde carbamate leading to the formation of 2-phenylpropenal. ALDH may oxidize the aldehyde carbamate to give CPPA [62]. Interestingly, species differences in the enzymes involved in the metabolism of felbamate are thought to have contributed to the lack of observed toxicity in preclinical studies. For example, in rats, 2-phenylpropenal formation is minor because of the significant P450-mediated metabolism of felbamate, the relatively poor esterase activity in rats, and the high ALDH activity in this species. The metabolic and chemical transformation uncovered in the numerous studies investigating felbamate toxicity present a fascinatingly complex example of non-P450 bioactivation.

3.4.3 Abacavir

Abacavir is a nucleoside reverse transcriptase inhibitor approved in 1999 for the treatment of HIV-1. Upon release onto the market, hypersensitivity reactions in ~4% of the patient population were reported. The severity of these reactions ranged from fever and rash to a small number of deaths [65]. In order to obtain a better understanding of the

potential for bioactivation pathways being responsible for this idiosyncratic reaction, characterization of the metabolism of abacavir was undertaken. The major metabolic routes for abacavir in humans were found to be O-glucuronidation and oxidation of the primary alcohol of abacavir to the carboxylic acid (Fig. 3.10). The latter conversion likely occurs via a two-step, four-electron oxidation to an aldehyde intermediate. However, this aldehyde was never directly observed in incubations and attempted synthesis failed, most likely the result of its instability/reactivity. On the basis of the likely intermediacy of this metabolite and the known reactivity of aldehyde metabolites, Walsh *et al.* hypothesized that either the aldehyde intermediate or an isomeric species where the cyclopentene double bond had tautomerized to give an α,β -unsaturated aldehyde were likely to blame for the hypersensitivity reactions [66].

In vitro metabolism studies were undertaken to provide evidence for the involvement of one or both of these pathways. These studies subsequently showed that the abacavir acid was only observed in human liver cytosol incubations and that the conversion, as well as covalent binding, was NAD^+ -dependent, suggesting the involvement of ADH [66]. Similar ADH-mediated four-electron oxidations of alcohols to acids previously have been reported [50].

Screening of purified ADH isoforms showed that only ADH1A and ADH1C were capable of forming carboxylic acid metabolites, as well as covalent binding. The observation of multiple isobaric species in the liquid chromatography/mass spectrometry (LC/MS) indicated that tautomerization of the cyclopentene double bond and/or racemization of one or more of the stereocenters likely had occurred. Trapping experiments with methoxylamine, resulting in the formation of an oxime species, provided support for the proposed aldehyde intermediate. Walsh *et al.* concluded that the mechanism of bioactivation for abacavir occurs via initial ADH-mediated oxidation to an unstable aldehyde metabolite. The double bond of the cyclopentene ring is then proposed to tautomerize into conjugation, giving an α,β -unsaturated aldehyde, which is likely to undergo Michael addition of protein nucleophiles. Studies using an analog of abacavir with the double bond of the cyclopentene reduced yielded similar metabolic turnover, but significantly limited covalent binding to protein. This result suggested that the unconjugated aldehyde alone had limited involvement in adduct formation via Schiff

Figure 3.10 Bioactivation of abacavir by ADH to α,β -unsaturated aldehyde.

base formation [66]. However, exploration of the reactivity of the α,β -unsaturated acid (which would likewise be a Michael acceptor) was not explored. Although these studies do not draw a conclusive link between reactive metabolites and toxicity, they do offer possible bioactivation pathways that could result in the observed idiosyncratic hypersensitivity of abacavir.

3.5 PEROXIDASES

Peroxidase enzymes (MPO, lactoperoxidase, and PGHS) are expressed in many tissues such as kidney medulla, platelets, GI tract, brain, lung, urinary bladder (PGHS), mammary gland epithelium (lactoperoxidase), and polymorphonuclear leukocytes (MPO). Thus, bioactivation of xenobiotics by PGHS appears to be more prevalent in these extra-hepatic tissues where various toxicities have been noted [67,68]. These enzymes are similar to cytochrome P450 enzymes in that they are hemoproteins and contain bound protoporphyrin IX, yet they do not require cofactors NADPH or NADH. Instead, peroxidases couple the reduction of hydrogen peroxide (H_2O_2) or lipid hydroperoxides to the oxidation of substrate (e.g., co-oxidation) [69]. Many xenobiotics have been shown to be oxidized by peroxidase enzymes, often to reactive metabolites. Typical classes of compounds that undergo peroxidase-mediated one-electron oxidation to potentially reactive intermediates include aromatic amines, phenols, hydroquinones, and polycyclic hydrocarbons. This section focuses mainly on PGHS and MPO.

3.5.1 Prostaglandin H Synthase (PGHS)

PGHS, most commonly referred to as *cyclooxygenase* (COX), exists in two forms: the constitutive enzyme (PGHS-1) that maintains normal housekeeping functions, and the inducible PGHS-2, which is involved in inflammatory processes, and as such, is the primary target for nonsteroidal anti-inflammatory drugs (NSAIDs). The physiological role of PGHS includes the initial oxidation of arachidonic acid to PGG₂ (e.g., *cyclooxygenase* activity), followed by a *peroxidase* activity, where the hydroperoxide group of PGG₂ acts as an oxygen donor to reduce PGG₂ to PGH₂ (Fig. 3.11). In parallel with the second peroxidase reaction, xenobiotics may undergo what is termed a co-oxidation reaction. It is this co-oxidation mechanism and the role it plays in bioactivation of xenobiotics that is of specific interest here. Three principle mechanisms of PGHS-mediated bioactivation have been characterized, as highlighted in Fig. 3.11, including (A) direct oxidation of the xenobiotic cosubstrate (typically phenols or amines) by the peroxidase, forming a radical and (B) direct oxidation by the peroxy radical (ROO•) that is generated during the cyclooxygenase reaction to form an oxygenated product. A third possible mechanism is a combination of mechanisms A and B, where the formation of a highly reactive radical species (formed during mechanism A) combines with oxygen (O_2) to form a peroxy radical which subsequently acts to bioactivate a secondary xenobiotic, as occurs in mechanism B (e.g., indirect bioactivation) [67]. Many chemicals, including aromatic amines, polyaromatic hydrocarbons (PAHs), aflatoxins, heterocyclic amines, and phenols, are capable of serving as electron donors during the peroxidase reaction. Mutagenicity assays are often used to assess the potential for the formation of mutagenic products, which may occur during PGHS-dependent oxidation of certain xenobiotics. This may be performed by incubating test compounds with *Salmonella*

Figure 3.11 Mechanism of PGHS-mediated bioactivation of xenobiotics.

bacterial tester strains, which contain ram seminal vesicle microsomes, a source of PGHS activity, in addition to arachidonic acid or hydrogen peroxide [67]. While specific examples of PGHS-mediated bioactivation are described in the following sections, a more comprehensive review of PGHS and its role in xenobiotic bioactivation has been published [69].

3.5.1.1 Acetaminophen (APAP). Metabolic activation of APAP by the cytochrome P450 enzymes to its reactive quinoneimine metabolite *N*-acetyl-*p*-benzoquinone imine (NAPQI) is well documented in the literature, and serves as the gold standard example of bioactivation of drug molecules. Formation of NAPQI in the liver is known to cause centrilobular necrosis upon overdose and depletion of cellular pools of detoxifying GSH [70]. In addition, and perhaps less recognized is that chronic exposure to APAP can also lead to covalent binding and damage in the kidney, a tissue that contains low levels of cytochrome P450 [71]. Ironically, it was noticed before fully understanding the mechanisms of bioactivation, that following pretreatment of mice and rats with the P450 inducer 3-methylcholanthrene, the induced changes were greater in the liver when compared to the kidney, suggesting that the formation of reactive metabolite in kidney was by a mechanism distinct from cytochrome P450 [72]. Subsequently, it was proposed that one-electron co-oxidation of APAP by PGHS in the renal medulla produces either the phenoxyl radical or the benzosemiquinoneimine radical (Fig. 3.12),

Figure 3.12 Bioactivation of acetaminophen to NAPQI in kidney medulla by PGHS.

leading to the eventual formation of NAPQI and regional injury in this tissue [73]. This serves as an excellent example of a tissue-specific toxicity due to bioactivation by a non-P450 enzyme highly expressed in that particular *microenvironment*, in this case, the kidney.

3.5.1.2 Aromatic Amines. Aromatic amines are ubiquitous in the environment, and are known as *human carcinogens* due to their oxidation to electrophilic intermediates and subsequent covalent modification of DNA. While the liver is often the main focus when studying bioactivation of aromatic amines, extrahepatic tissues such as urinary bladder contains low expression levels of cytochrome P450, while PGHS levels are quite high in both humans and dogs [74]. Aromatic amines such as benzidine, 4-aminobiphenyl, and 2-aminonaphthalene are reported to be bioactivated by PGHS to mutagenic reactive metabolites, such as diimines (Fig. 3.13) that can interact with DNA. This is presumed to be the mechanism by which aromatic amines lead to carcinogenesis

Figure 3.13 Bioactivation of aromatic amine benzidine, polyaromatic hydrocarbon BaP, and hydantoin phenytoin by PGHS leading to various forms of carcinogenesis/teratogenesis.

in the bladder and other tissues [68,75,76]. Specifically, the bioactivation of radiolabeled benzidine to detectable DNA-bound products in various extrahepatic tissues has been investigated. For example, covalent binding to DNA was observed in microsomal preparations from urinary bladder epithelium, prostatic epithelium, colonic mucosa, and peripheral lung tissue [74]. The role of PGHS in the bioactivation of benzidine was supported by the data showing that binding was dependent on the presence of arachidonic acid, and was also inhibited substantially when coincubated with indomethacin, a known inhibitor of PGHS. This bioactivation pathway likely has played a role in the high frequency of bladder cancer in workers who have been continuously exposed to aromatic amines in the chemical and rubber industries, as well as in smokers [77].

3.5.1.3 Polyaromatic Hydrocarbons (PAHs). PAHs are ubiquitous in the environment, found in oil and as by-products of fuel burning. These molecules are of significant concern because of their highly carcinogenic nature and essentially unavoidable exposure by the general population. Formation of the active carcinogenic form generally requires metabolic oxidation of the PAH by the cytochrome P450 enzymes, the most

well characterized of which is benzo[*a*]pyrene (BaP). As shown in Fig. 3.13, BaP is oxidized by the cytochrome P450 enzyme system to the 7,8-epoxide, which is then subsequently converted by epoxide hydrolase to the 7,8-dihydrodiol. It is the 7,8-dihydrodiol of BaP that may then be co-oxidized by PGHS via the peroxy radical mechanism (mechanism B) highlighted in Fig. 3.11 to form the ultimate carcinogen, the bay region 7,8-diol-9,10-epoxide. Interestingly, only dihydrodiols with double bonds adjacent to the bay region are mutagenic with PGHS, demonstrated with multiple PAHs including BaP, benzo[*a*]anthracene, and chrysene [78]. In addition, PGHS-mediated epoxidation of BaP-7,8-diol is reported to be catalyzed by microsomes generated from several known target organs of BaP-induced tumorigenesis, including mouse skin and rat and human lung [79], again highlighting the common link between the region of bioactivation and observed toxicity. Another relevant example of bioactivation of an environmental procarcinogen is aflatoxin B1, which is converted to the mutagenic 8,9-epoxide by PGHS (and lipoxygenases) in the human lung [80].

3.5.1.4 Hydantoins. Phenytoin is a commonly used anticonvulsant that happens to also be teratogenic in animals, as well as humans [81]. For years, the molecular mechanism of teratogenesis by phenytoin, as well as the structurally related thalidomide, has remained elusive. What has been discovered in recent years is that both phenytoin and thalidomide may be bioactivated by embryonic PGHS (highly active in embryo during organogenesis) to free radical intermediates. Specifically, phenytoin and its analogs mephenytoin and trimethadione may be bioactivated to an imidyl nitrogen-centered radical that can undergo ring opening to a carbon-centered radical with an isocyanate moiety (Fig. 3.13). These radicals may either bind to critical embryonic DNA and/or proteins or initiate embryonic reactive oxygen species (ROS) formation that can result in oxidative stress [82]. Evidence supporting this biochemical mechanism includes characterization of free radical spin adducts that were absent in control incubations, as well as when a PGHS inhibitor was included in the incubation. Similarly, for the well-characterized teratogen thalidomide, pretreatment of rabbits with the spin trapping agent α -phenyl-*N*-*t*-butylnitrone (PBN) essentially blocked both thalidomide-mediated embryonic DNA oxidation and teratogenicity *in vivo* [83], which provides strong evidence for a free radical intermediate generated by a non-cytochrome P450 enzyme as a relevant molecular mechanism of teratogenicity.

3.5.2 Myeloperoxidase (MPO)

A major oxidation system in leukocytes (e.g., neutrophils and monocytes) is the combination of NADPH oxidase and MPO. In this complex system, summarized in Fig. 3.14, hydrogen peroxide (H_2O_2), which is generated following dismutation of NADPH oxidase-mediated superoxide ($\text{O}_2^{\cdot-}$) oxidizes the MPO enzyme to a form referred to as *Compound I*. Compound I can in turn oxidize chloride ion (Cl^-) to hypochlorous acid (HOCl), the primary oxidant in neutrophils, which can oxidize or chlorinate drug molecules. In general, the MPO enzyme system is capable of oxidizing xenobiotics with easily oxidizable functional groups [84,85], including aromatic amines, hydrazines, and sulfur compounds, in many cases leading to the formation of reactive chlorinated intermediates. This enzyme system has thus been reported to play a dominant role in the formation of reactive metabolites of drugs that cause certain blood disorders such as agranulocytosis, where neutrophils are the target of toxicity, and

Figure 3.14 Mechanism of MPO-mediated chlorination of xenobiotics in neutrophils.

drug-induced lupus [85], both of which may occur in an idiosyncratic manner. While we concentrate only on selected examples of MPO-mediated bioactivation of xenobiotics, reports of this mechanism in the literature are numerous, and thus, the reader is directed to more focused reviews on this particular enzyme system present in leukocytes [84–86].

3.5.2.1 Diclofenac. Diclofenac is a widely prescribed NSAID that has been associated with cases of severe hepatotoxicity [87]. In addition, rare cases of neutropenia and thrombocytopenia have been observed [88,89], which has triggered interest in the ability of diclofenac to be bioactivated to reactive intermediates in neutrophils, the target of observed toxicities. In an *in vitro* system including MPO/H₂O₂/Cl⁻, as well as activated neutrophils, Miyamoto *et al.* found evidence for the formation of a reactive quinoneimine (Fig. 3.15), proposed to be formed following N-chlorination and oxidation to 5-hydroxydiclofenac [90]. It is thus hypothesized that this reactive metabolite generated in neutrophils may be involved in the idiosyncratic reactions reported with the use of diclofenac. Interestingly, the structurally related COX-2 inhibitor lumiracoxib, which was recently withdrawn from the market in many countries because of severe liver toxicity, has also been reported to undergo similar mechanisms of bioactivation to quinone-imines, both by cytochrome P450, as well as peroxidases MPO and PGHS [91]. Other drugs associated with various toxicities that appear to form quinoneimine intermediates via peroxidase mechanisms include amodiaquine and APAP [86].

3.5.2.2 Ticlopidine. Ticlopidine is an antiplatelet drug that has essentially been supplanted by clopidogrel (Plavix®) due to the significant incidences of agranulocytosis [92]. Ticlopidine contains a thiophene ring, a known structural alert for bioactivation (e.g., tienilic acid and suprofen), and in addition to cytochrome P450-mediated

Figure 3.15 Bioactivation of diclofenac, ticlopidine, and clozapine by MPO.

reactive metabolite formation, it has been shown that ticlopidine may be metabolized by MPO and in activated neutrophils to a reactive *S*-chloride metabolite [93]. As Fig. 3.15 illustrates, the *S*-chloride of ticlopidine is reported to likely undergo several subsequent reactions, including with the nucleophilic chloride ion (Cl⁻) to form the proposed 2-chloroticlopidine, loss of HCl to form the predominantly observed dehydro-ticlopidine metabolite, and with GSH to form the proposed conjugate with GSH at the 2-position [93].

3.5.2.3 Clozapine. Clozapine is an antipsychotic agent that has restricted use because of a high incidence (1%) of agranulocytosis [94]. Similar to the previously mentioned examples, clozapine was found to be bioactivated to a reactive species in both the MPO/H₂O₂/Cl⁻ system, as well as in activated neutrophils [95]. In addition, covalent binding to neutrophils was observed following incubation with radiolabeled clozapine. The reactive species was proposed to be a delocalized nitrenium ion (Fig. 3.15), formed through a purported *N*-chloro intermediate (not observed directly), which reacted with GSH to form two GSH conjugates. Structure-activity characterization of clozapine and some close analogs has also been reported [96]. Replacement of the nitrogen that connects the two aryl rings on clozapine with oxygen or sulfur resulted in analogs that did not undergo peroxidase-mediated bioactivation to the reactive iminium species in neutrophils, which supports the proposed mechanism. The benefit to this chemical intervention is apparent in the drugs quetiapine (sulfur instead of bridging nitrogen) and loxapine (oxygen instead of bridging nitrogen), both of which have been in clinical use without a high incidence of adverse events.

3.6 ALDO-KETOREDUCTASES (AKR)

The aldo-ketoreductase (AKR) enzymes are a superfamily of NADPH-dependent cytosolic enzymes that catalyze the reduction of aldehydes and ketones to primary and secondary alcohols, respectively. These enzymes may also utilize NADP⁺ in the oxidation of certain xenobiotics, particularly of alcohols. This is a complex family of enzymes, as there are roughly 114 proteins in the AKR superfamily that are distributed over 14 families (AKR1–AKR14), and expressed widely in liver and brain of prokaryotes and eukaryotes [97]. AKR enzymes are generally thought to be involved in detoxification of xenobiotics, but from a chemical toxicology point of view, some members of the AKR family have been implicated in the oxidation of xenobiotics to carcinogenic metabolites, one of which is dihydrodiol dehydrogenase (DD), a member of the AKR1C subfamily.

3.6.1 Polyaromatic Hydrocarbons (PAHs)

As already described in Section 3.5 of this chapter, PAHs such as BaP are primary environmental pollutants, with the bioactivation pathways of BaP to the proposed carcinogen, BaP 7,8-diol-9,10 epoxide, being catalyzed by cytochrome P450 and peroxidases such as PGHS. An often overlooked alternate bioactivation pathway in this cascade is the NADP⁺-dependent *oxidation* of the 7,8-diol of BaP by DD, which produces the unstable catechol of BaP (Fig. 3.16). This catechol can then undergo auto-oxidation with superoxide to yield hydrogen peroxide (H₂O₂) and the *o*-semiquinone anion radical, with eventual production of the reactive *o*-quinone, BPQ [98], a Michael acceptor that can form adducts with cellular nucleophiles such as DNA [99]. In addition, BPQ can undergo a two-electron reduction back to the catechol using cellular reducing equivalents (NADPH), which may initiate a futile redox cycle, triggering multiple rounds of ROS formation and leading to further DNA damage and tumor initiation [100]. Additional studies where cDNAs were isolated from HepG2 cells have shown that there are four DD isoforms in the liver (DD1, DD2, DD4, and DDX) that are capable of contributing to PAH bioactivation to reactive *o*-quinones [101]. Other PAHs that have also been studied in this context include 1,2-dihydronaphthalene-1,2-diol and benz[*a*]anthracenedihydrodiols [102,103]. Convincing evidence for the role of AKR enzymes in human lung carcinogenesis includes the finding that AKR1C enzymes are expressed in the human lung carcinoma cell line A549, and 7,12-dimethylbenz[*a*]anthracene-3,4-diol (DMBA-3,4-diol) was found to convert to the *o*-quinoneDMBA-dione within A549 cells, trapped as the mono- and bis-thioether conjugates [104]. Thus, the human AKR enzymes appear to be an important family of drug-metabolizing enzymes contributing to the metabolic activation of various PAHs to carcinogenic metabolites.

3.7 REDUCTIVE BIOACTIVATION

Bioactivation of drugs may also proceed via reductive metabolic pathways, particularly reduction of nitroaromatic-containing drugs, which typically involves a six-electron reduction of the nitro group to the aniline, which often results in the formation of mutagenic metabolites [105]. Reductive metabolism of nitroaromatics can be catalyzed

Figure 3.16 Bioactivation of BaP 7,8-dihydrodiol to catechol by the AKR1C enzyme dihydrodiol dehydrogenase, leading to futile cycling and ROS generation.

not only by cytochrome P450, but also by NADPH cytochrome P450 reductase (CPR), xanthine oxidase (XO), AO, nitric oxide synthase (NOS), and quinonereductases such as NQO1 [106]. Given the broad enzyme overlap in the substrate specificity for many of the reductive pathways, we highlight a couple of specific enzymes and make mention of others if a role has been observed.

3.7.1 NADPH-Quinoneoxidoreductase (NQO1)

NADPH-quinoneoxidoreductase (NQO) is a cytosolic flavoprotein that is also commonly referred to as *DT-diaphorase* (DTD) [107]. It is a dimer of two equal subunits, each containing FAD, and is highly expressed in the stomach and kidney, but also in the lung, liver, and intestinal tract [108]. Humans appear to express four forms of DTD, the fourth being the predominant form, the inducible NQO1 [107]. The role of this enzyme is typically in the two-electron reduction of quinones to the relatively stable hydroquinone, a competing detoxification pathway leading to cytoprotection against potentially toxic semiquinones that may be formed via one-electron reduction by enzymes such as NADPH-CPR. The two potential reductive pathways are depicted with menadione in Fig. 3.17. Despite a predominant role in detoxification, there are examples where NQO1 bioactivates drug molecules to reactive metabolites, which ironically, in some cases may be of potential therapeutic benefit, as described in the latter part of this section.

3.7.1.1 Aristolochic Acid. Aristolochic acid (AA) is a plant extract and a component of many Chinese herbs [109] that has been associated with the development of nephrotoxicity in humans, often referred to as *aristolochic acid nephropathy* (AAN), including

Figure 3.17 Reductive pathways for menadione, including the one-electron reduction to the semiquinone radical by CPR and two-electron reduction to the inert hydroquinone by DT-diaphorase.

urothelial cancer [110]. The two main components of AA are 8-methoxy-6-nitro-phenanthro-(3,4-*d*)-1,3-dioxolo-5-carboxylic acid (AAI) and 6-nitro-phenanthro-(3,4-*d*)-1,3-dioxolo-5-carboxylic acid (AAII), as shown in Fig. 3.18. AA has been reported to form covalent DNA adducts, which have been observed in patients with AAN [111,112]. Consistent with the structures of the major DNA adducts identified [113], the initial step in the bioactivation pathway of these naturally occurring nitroarenes to their carcinogenic species appears to be a multistep nitro reduction to an eventual lactam intermediate, followed by nitrenium ion formation (Fig. 3.18). It is unclear what the actual reactive precursor is that forms the lactam. Characterized adducts supporting this pathway include 7-(deoxyadenosin-*N*6-yl)aristolactam I and II (dA-AAI and dA-AAII) and 7-(deoxyguanosin-*N*2-yl)aristolactam I (dG-AAI), which have been used as standards to evaluate which human renal and hepatic cytosolic enzymes are involved in the bioactivation (e.g., nitro reduction) of AA to form these specific adducts. Reported data supports a dominant role for NQO1 in the formation of these DNA adducts, as incubations carried out in the absence and presence of dicoumarol, a potent inhibitor of NQO1, resulted in an 85% decrease in the levels of AAI-DNA adducts in hepatic cytosol, and 75% decrease in renal cytosol [114]. Interestingly,

Figure 3.18 Reductive bioactivation of aristolochic acid by NQO1 to the cyclic nitrenium intermediate.

AA has also been reported to be bioactivated by other reductive enzymes, such as XO, as well as peroxidases such as PGHS [115,116], while the expected cytochrome P450-mediated bioactivation of the methylenedioxyphenyl moiety to either a carbene or catechol has not been reported.

3.7.2 NADPH Cytochrome P450 Reductase (CPR)

NADPH-CPR is also known as *NADPH:ferrihemoprotein oxidoreductase*, NADPH: hemoprotein oxidoreductase, NADPH:P450 oxidoreductase, or P450 reductase. CPR is a membrane-anchored enzyme found in the endoplasmic reticulum of cells and is widely expressed throughout the body, although it is most abundant in the liver [117]. Initial establishment of the involvement of CPR for P450 activity came from the work of Lu *et al.* [118,119], who performed the first resolution of P450, CPR, and lipid from rabbit liver microsomes. Subsequently, CPR was found to be required for the transfer of electrons to hemeoxygenase, cytochrome *b*₅, squalenemonooxygenase, and 7-hydroxycholesterol reductase [120]. Additionally, CPR can itself catalyze the metabolism of drugs [121,122].

3.7.2.1 Paraquat. Paraquat (PQ) is a commonly used, fast-acting herbicide. Since its introduction in 1962, numerous accidental or voluntary ingestions have occurred resulting in numerous fatalities and even more cases of “paraquat lung.” In addition to the major site of toxicity in the lung; the kidney, the liver, and the thymus also are affected by PQ [123].

Upon ingestion, PQ is rapidly absorbed and accumulated via a polyamine uptake system into the lung. In the lung, PQ undergoes an alternating process of reduction and oxidation, also known as *redox cycling* [106]. The major reductive enzymes involved in PQ reduction to the cation radical PQ^{•+} are CPR, NADH:ubiquinone oxidoreductase, XO, and NOS [124]. The rapid reoxidation of PQ^{•+} by O₂ in the lung occurs because of the high aveolar pressure, resulting in generation of O₂^{•-}. Subsequently, available NADPH is utilized to reduce O₂^{•-}. The end result of these events include generation of ROS (e.g., peroxide, superoxide, and hydroxyl radical), oxidation of cellular thiols, depletion of GSH stores, and oxidative damage to lipids, proteins, and DNA [124].

3.7.2.2 Flutamide. Flutamide is a nonsteroidal antiandrogen used for the treatment of prostate cancer. Reports of idiosyncratic hepatotoxicity range between 1% and almost 10% of patients treated with flutamide [125,126]. Symptoms of liver dysfunction include elevation of serum aminotransaminase (ALT) and bilirubin, hepatic necrosis, and cholestasis [125]. The major routes of metabolism for flutamide include hydroxylation, hydrolysis, N-acetylation, and nitro reduction (Fig. 3.19). The prominence of nitro-reduction steps in the metabolism of flutamide as well as the established toxicity/reactivity of nitro-reduction intermediates lead Wen *et al.* to hypothesize that reduction of the nitro group was involved in the toxicity of flutamide [127]. On the basis of this hypothesis, flutamide and an analog where the nitro group was replaced with a cyano group, were examined in a hepatocyte toxicity assay [128]. These studies demonstrated time- and concentration-dependent toxicity which was approximately twofold greater for flutamide than its cyano analog. Subsequent to these toxicity studies, Wen *et al.* thoroughly profiled the metabolites of flutamide and its cyano analog in human liver microsomes and human hepatocytes. Similar oxidative GSH adducts were

Figure 3.19 Nitro-reductive bioactivation of flutamide by CPR.

detected for both compounds. However, several GSH adducts resulting from reduction of the nitro group were observed only for flutamide. Incubation of the *p*-aniline compound, which would result from nitro reduction, gave these same GSH adducts suggesting the possibility of a reactive diamine species. Additionally, the observed reduction of the nitro group may also implicate toxicity via redox cycling [106].

An interesting finding by Wen *et al.* is that the nitro reduction was solely carried out by CPR under aerobic and anaerobic conditions. Furthermore, a dramatic increase in the rate of the formation of the aniline metabolite was observed under anaerobic conditions using both microsomes and expressed CPR. The involvement of P450s in the reduction of the nitro group was ruled out using specific inhibitors of P450 and expressed enzymes. Likewise, cytochrome *b₅* reductase (another known *nitroreductase*) was shown not to reduce the nitro group of flutamide in microsomal incubations supported by NADH. Further confirmation of CPR involvement comes from the >90% inhibition of the formation of the nitro-reduced metabolite in microsomes, coincubated with α -lipoic acid, a selective and reversible CPR inhibitor. Although these studies supply convincing evidence for the involvement of CPR, the involvement of other cytosolic or mitochondrial “nitroreductases” could not be ruled out.

3.7.3 Bioreductive Antitumor Prodrugs

Contrasting the multitude of examples of bioactivation described to this point, reductive bioactivation to cytotoxic intermediates may actually be used as a therapeutic strategy. Some chemotherapeutic agents such as mitomycin C, tirapazamine (TPZ) (SR4233), and CB 1954 are reductively bioactivated to cytotoxic metabolites that can cause DNA strand breaks, a mechanism referred to broadly as *bioreductive activation* [129]. These

drugs must be a substrate for one-electron reductases that effectively convert the compound to a free radical (Fig. 3.20). Thus, these are considered “prodrugs.” Bioreductive activation mechanisms within tumor cells offer a novel chemotherapeutic strategy to medicinal chemists who are attempting to selectively target and kill cancerous tumor cells. The apparent selectivity of this bioactivation mechanism is due in part to tumor cells possessing hypoxic regions (e.g., lacking oxygen), which are typically resistant to chemotherapy and radiotherapy, contributing to cancer progression. In a cell with normal oxygen levels, the resulting free radical formed rapidly transfers the unpaired electron to oxygen to form superoxide (Fig. 3.20), which may be scavenged by reactive oxygen scavenging enzymes such as superoxide dismutase and catalase. Conversely, in a hypoxic environment, the generated radical may accumulate to cytotoxic levels within the cell. Interestingly, hypoxia leads to an elevation in the expression of some reductive enzymes such as CPR, relative to normal cells [130], which in addition to the hypoxic environment, may yield selectivity for this reductive mechanism in those types of cells.

3.7.3.1 Tirapazamine. TPZ is one of the most promising hypoxia-selective anti-tumor drug molecules to date [131], with 50–300 times higher toxicity observed in hypoxic cells as compared to normally oxygenated cells [132]. TPZ contains two *N*-oxide functionalities that may undergo a one-electron reduction to form the radical anion which exists in equilibrium with the protonated nitroxide radical (TPZ[•]) [131,133]. As previously mentioned, in an environment where oxygen is present, this radical can donate its electron back to oxygen to form superoxide, rendering TPZ essentially nontoxic. However, under hypoxic conditions, investigations within the Gates’ lab support a mechanism by which the neutral TPZ radical product undergoes homolytic fragmentation to produce the DNA damaging hydroxyl radical (HO[•]) [134]. It has also been reported that the TPZ radical may undergo dehydration to form the oxidizing benzotriazinyl radical (Fig. 3.20), leading to DNA damage [135]. The exact chemical mechanisms for TPZ-mediated DNA damage remain under investigation.

From an enzymology standpoint, a role for both CPR and NOS has been demonstrated in the reductive activation of TPZ [136,137]. It is worth noting that the (NOS) enzyme has both an oxidase and a reductase domain, with its reductase domain sharing strikingly similar homology with CPR [138], likely contributing to the observed overlapping substrate selectivity in this example. In addition, TPZ is reported to be a substrate for two- or four-electron reduction by DTD [107], which as described earlier with menadione, may lead to the nonradical inactive product, providing a potential detoxification mechanism, and complicating selective bioactivation to the necessary cytotoxic radical in tumor cells. Numerous phase II/III clinical studies have been performed evaluating the effectiveness of this bioreductive prodrug approach, with mixed results [139,140], indicating the complexity in utilizing these mechanisms in cancer therapy. Nonetheless, the promise remains that TPZ could be a viable therapeutic option in the treatment of cancer.

3.7.3.2 Mitomycin C and CB 1954. Mitomycin C and CB 1954 have also been among the bioreductive prodrug design effort, and they undergo quinone reduction and nitro reduction, respectively (Fig. 3.20). Mitomycin undergoes reduction to its radical anion by both CPR and the molybdenum-containing enzyme XO [141]. Formation of the radical anion facilitates aromatization of the quinone ring and loss of methanol,

N-Oxide Reduction

Quinone Reduction

Nitro Reduction

Figure 3.20 Examples of bioreductive activation of antitumor prodrugs tirapazamine, mitomycin C, and CB 1954 by numerous reductive pathways.

due in part to the resonance stabilization, which then enables nucleophilic attack at the C1 carbon and potential for DNA damage. As mentioned, a critical necessity of the bioreductive prodrug approach in anticancer therapy to minimize toxicity in non-targeted cells is selective bioactivation of the prodrug in the tumor. This challenge is highlighted by CB 1954, an antitumor prodrug that demonstrated dose-limiting hepatotoxicity in Phase I clinical studies [142]. *In vitro* studies aimed at understanding whether CB 1954 could undergo reductive bioactivation in human liver found that nitro reduction at both the 2- and 4-positions occurred in S9 and cytosolic fractions, as well as microsomes, with the potent cytotoxic 4-hydroxylamine being the predominant metabolite [143], which can react with acetyl CoA to form a potent DNA crosslinking agent (Fig. 3.20). During enzyme phenotyping studies, it was observed that carbon monoxide, an inhibitor of P450, decreased metabolite formation in human liver S9, and CB 1954 metabolites were observed in microsomes supplemented with the cofactor NADH. This supports *b*₅ reductase activity, indicating that multiple reductive hepatic enzymes are likely involved to some degree in the nitro reduction of CB 1954 [143]. Owing to the complexities of bioreductive activation, namely, competing deactivation pathways and noted species differences in the reduction of CB 1954 [144], the search for more selective bioreductive prodrugs appears extremely challenging, but is ongoing.

3.8 CONCLUSIONS AND PERSPECTIVES

While bioactivation of drug molecules to reactive metabolites is most commonly associated with the cytochrome P450 enzyme system, this chapter highlights that examples of bioactivation of xenobiotics by non-P450 drug-metabolizing enzymes are plentiful and should not be overlooked. Contributing to the potential for oversight is that drug-discovery programs typically conduct the majority of their screening for metabolism and reactive intermediates using microsomes from liver (the location where majority of drug metabolism occurs). This approach only addresses the potential risks of reactive metabolite formation in the liver by a limited number of metabolic enzymes (e.g., cytochrome P450 and FMO). Highlighted in this chapter is that extrahepatic toxicities may also occur via non-P450-mediated bioactivation event(s), particularly in the tissue where these enzymes are expressed, such as PGHS and its purported role in bioactivating APAP to its NAPQI intermediate in the kidney. Table 3.2 summarizes the additional examples described in this chapter, highlighting the xenobiotic, functional group bioactivated, reactive intermediate formed, and the target tissue for toxicity, if in fact reported. Equally relevant may be the absence of a detoxification pathway in a particular tissue, such as the lack of AO activity in brain where MPTP illicitly its untoward effects. This suggests that for more thorough profiling of the metabolism and risk of generation of reactive metabolites, different tissue fractions, or even purified enzymes should be used, in addition to those which are typically available. Overall, it is the opinion of these authors that while there is no perfect “catch-all” *in vitro* system for evaluating the risk of bioactivation of drug molecules, familiarity with the non-cytochrome P450 drug-metabolizing enzymes, in combination with an understanding of chemical moieties that are susceptible to bioactivation by these enzymes, should lead to more informed chemical modification during drug candidate optimization.

TABLE 3.2 Summary of Xenobiotics Presented in this Chapter that are Bioactivated by Non-P450 Enzymes and the Toxicities Associated with Reactive Intermediate Formation

Enzyme	Xenobiotic	Bioactivated Moiety	Reactive Intermediate	Target of Toxicity
FMO	Thiobenzamide	Thioamide	Iminosulfinic acid	Lung Skin Kidney
	Ketoconazole	Aryl piperazine	Nitrone	Liver
MAO	MPTP	4-Fluoro- <i>N</i> -methyl aniline	Quinoneimine	Brain
	Dopamine	Pyridine	Pyridinium	
SSAO	Allylamine	Amine	Aldehyde	Brain
ADH	Allyl alcohol	Amine	Aldehyde	Heart
	Felbamate	Alcohol	Aldehyde	Heart
PGHS	Abacavir	Aldehyde carbamate	2-Phenylpropenal	Liver Blood
	APAP	Alcohol	Aldehyde	Skin
	Benzidine 2-naphthylamine	Phenol	Free radical/NAPQI	Kidney
	PAH	Aromatic amines	Diimine	Bladder
	Phenytoin	Aromatic ring	Epoxide	Lung
MPO	Diclofenac	Hydantoin	Radical	Teratogen
	Ticlopidine	Secondary arylamine	Quinoneimine	Blood
	Clozapine	Thiophene	<i>S</i> -chloride	Blood
	PAH	Secondary nitrogen	Nitrenium	Blood
AKR	Aristolochic acid	Diols	<i>ortho</i> -quinone	Lung
NQO1	Paraquat	Nitro	Nitrenium	Kidney
CPR	Flutamide	Pyridinium	Radical	Lung
	Tirapazamine	Nitro	Diimine	—
CPR, NOS		<i>N</i> -oxide	Benzotriazinyl radical, hydroxide radical	Tumor cell
CPR, XO, <i>b</i> ₅ reductase	Mitomycin C	Quinone	Anion radical	Tumor cell
	CB 1954	Nitro	Hydroxylamine	Tumor cell Liver

4.1 SUMMARY

Phase-II-enzyme-catalyzed conjugation of xenobiotics most often leads to detoxification but can also mediate their bioactivation to chemically reactive and potentially toxic metabolites. Chemically reactive metabolites of xenobiotics, including drugs and environmental chemicals, are generated most often by oxidative metabolism (e.g., phase-I-mediated cytochrome P450-mediated oxidative bioactivation), which can lead to covalent binding to protein and/or nucleic acids. In some cases, this process leads to intrinsic (acute) and/or idiosyncratic (immune mediated) toxicity and carcinogenicity. However, additional biotransformation routes, such as phase-II-mediated conjugation reactions, can also play a role in the formation of chemically reactive electrophilic conjugates that are toxic. Phase II metabolism encompasses processes including glucuronidation, sulfonation, acetylation, amino acid conjugation, glutathione (GSH) conjugation, methylation, and phosphorylation. Xenobiotics and/or xenobiotic metabolites can be conjugated with endogenous cofactors leading to hydrophilic derivatives that, in most cases, function to eliminate and detoxify xenobiotics from the body. For example, the intrinsic toxin acetaminophen is detoxified by glucuronidation

and sulfonation leading to highly water-soluble, unreactive, oxygen-linked glucuronide and sulfonate metabolites, respectively, that are efficiently excreted from the body. However, despite the well-established classical role of phase-II-enzyme-catalyzed xenobiotic detoxification, the metabolic activation of drugs or drug metabolites by phase II metabolism in some cases leads to the formation of highly reactive conjugates capable of mediating the covalent binding of drug equivalents to protein and/or DNA. The major conjugation reactions known to be involved in xenobiotic bioactivation are glucuronidation, sulfonation, acetylation, GSH conjugation, and acyl-S-CoA formation. Glucuronidation of xenobiotics leads to the formation of electrophilic glucuronides, such as acyl glucuronides formed from carboxylic-acid-containing xenobiotics as well as endogenous compounds and N- or N-O-linked glucuronides formed from arylhydroxamic acids. Metabolic activation by O-sulfonation of chemicals such as polycyclic aromatic benzylic alcohols, allylic alcohols, *N*-arylhydroxylamines, and *N*-acetyl-*N*-arylhydroxylamines leads to the formation of chemically reactive nitrenium ion and carbocation species that can covalently bind to and damage DNA. The N-acetylation of xenobiotic aromatic hydrazines and aromatic amines can function as a preliminary step in the bioactivation of protoxicants to chemically reactive intermediates that are proposed to induce hepatotoxicity or carcinogenesis by covalently binding to protein or DNA. Conjugation with GSH can lead to the formation of chemically reactive toxic conjugates that mediate oxidative stress and/or covalent binding to important macromolecules, leading to hepatic, kidney, and even CNS injury. Amino acid conjugation of carboxylic-acid-containing drugs is mediated by acyl-S-CoA formation and can lead to the production of reactive acyl-linked intermediary metabolites that covalently bind to protein via transacylation, which has been proposed to be responsible, at least in part, for mediating idiosyncratic toxicity. In summary, this chapter deals with the known mechanisms of formation of chemically reactive xenobiotic metabolites, which are mediated by phase-II-drug-conjugating enzymes that can lead to tissue toxicity rather than xenobiotic detoxification.

4.2 INTRODUCTION TO PHASE-II-MEDIATED BIOACTIVATION

4.2.1 Classification of Xenobiotic Metabolism

Xenobiotic metabolism has long been classified as occurring by two distinct phases, namely, phase I (functionalization) and phase II (conjugation) [1,2]. Phase I biotransformation reactions include the oxidation, reduction, or cleavage of a xenobiotic functional group. Phase II reactions encompass the conjugation of a functional group of a xenobiotic or a xenobiotic phase I metabolite with endogenous substances such as glucuronic acid, sulfate, acetate, GSH, or an amino acid such as glycine. Both phase I and phase II metabolic transformations function most often to provide increased aqueous solubility and, therefore, provide increased excretion efficiency of xenobiotics into urine and/or bile, thus affording mechanisms by which they can be eliminated and detoxified from the body. In his classic book "Detoxification mechanisms: The metabolism and detoxication of drugs, toxic substances and other organic compounds," R. T. Williams [1] stated "... phase-I reactions cannot be considered as detoxication mechanisms although in many cases detoxication does occur as a result of these reactions. Phase II reactions, on the other hand, appear to be largely processes of detoxication but again

exceptions occur.” It is now well known that the metabolism of xenobiotics by phase I and phase II reactions, and sometimes a combination of both, can be toxicologically significant. An important hypothesis that was established during the 1960s and 1970s proposed that in order for some xenobiotics to induce carcinogenesis, they first must undergo phase-I-mediated metabolic activation by cytochrome P450s to chemically reactive species [3]. It was stated that chemically reactive hard electrophiles, such as carbocations, nitrenium ions, or iminium ions, react with hard nucleophiles located in nucleic acids, leading to DNA damage [4]. For example, cytochrome P450 is a major phase-I-drug-metabolizing family of enzymes that can function in the bioactivation of xenobiotics to form chemically reactive metabolites, such as epoxides, quinones, quinone imines, quinonemethides, imine methides, and nitroso intermediates, that lead to covalent binding to cellular macromolecules and, in some cases, can result in organ toxicity or carcinogenesis [5]. Other phase I metabolism enzymes can also function in the bioactivation of xenobiotics; for example, the flavin-dependent monooxygenases-mediated bioactivation of 4-fluoro-*N*-methylalanine [6], the alcohol-dehydrogenase-mediated metabolic activation of abacavir [7], and the monoamine-oxidase-mediated bioactivation of haloperidol [8].

4.2.2 Phase-II-Mediated Pathways of Xenobiotic Metabolic Activation

There are numerous examples where phase II enzymes have been shown to be important in the metabolic activation of xenobiotics to toxic metabolites (Table 4.1). Phase II enzymes known to be involved in the bioactivation of xenobiotics include UDP-glucuronosyltransferases (UGT), cytosolic sulfotransferases (SULT), *N*-acetyltransferase (NAT), GSH *S*-transferases, and acyl-*S*-CoA synthetases. These phase II enzymes are increasingly being shown to mediate the bioactivation of promutagens, procarcinogens, and protoxicants, leading to the formation of chemically reactive electrophiles that bind covalently to DNA, RNA, and protein [9].

Glucuronidation functions in the conjugation of glucuronic acid to a xenobiotic, which sometimes leads to the generation of chemically reactive intermediates [30]. For example, the glucuronidation of carboxylic acid drugs leads to the formation of acyl glucuronides that are able to covalently bind to cellular macromolecules including proteins and DNA via transacylation and Schiff base formation. The *N*-glucuronidation of *N*-hydroxylated metabolites of aromatic-amine-containing xenobiotics leads to unstable *N*-glucuronides that decompose to highly reactive nitrenium-ion-containing intermediates, which covalently bind to and damage DNA. The varied types of toxicities that are proposed to be mediated by chemically reactive glucuronide conjugates include idiosyncratic hypersensitivity, bladder cancer, and gastroenteropathy [30].

Sulfonation of promutagens and procarcinogens that have chemical moieties such as polycyclic aromatic benzylic alcohol, allylic alcohol, *N*-arylhydroxylamine, and *N*-acetyl-*N*-arylhydroxylamine leads to unstable sulfonate esters that decompose to chemically reactive benzylic or allylic carbocations and nitrenium ions, respectively, which are able to react with nucleic acids leading to carcinogenesis [31].

The *N*-acetylation of protoxicants containing aromatic hydrazine or aromatic amine substructures can serve as the first step in their metabolic activation to chemically reactive intermediates, such as highly reactive acylating acetyl radical species or reactive nitrenium ions, which covalently bind to protein and nucleic acids leading to hepatotoxicity or carcinogenesis [17].

TABLE 4.1 Metabolic Reactions Involved in the Phase-II-Mediated Bioactivation of Xenobiotics

Phase II Reaction	Enzyme	Cofactor	Functional Group	Reactive Intermediate	Example	References
Glucuronidation	UDP-glucuronosyl-transferases	UDPGA	Carboxylic acids	Acyl glucuronide	Diclofenac	10
			Arylhydroxamic acids	N–O-linked glucuronide (nitrenium ion)	<i>N</i> -Hydroxy-2-AAF	11
Sulfonation	Sulfotransferases	PAPS	Benzylic alcohols	Benzylic sulfonate esters (benzylic carbocation)	7-OH-DMBA	12
			Allylic alcohols	Allylic sulfonate esters (allylic carbocation)	Tamoxifen	13
			<i>N</i> -Aryl-hydroxylamines	<i>N</i> – <i>O</i> -sulfonate ester (nitrenium ion)	<i>N</i> -hydroxy-MAB	14
			<i>N</i> -Acetyl- <i>N</i> -aryl-hydroxylamines	<i>N</i> – <i>O</i> -sulfonate ester (nitrenium ion)	<i>N</i> -hydroxy-2-AAF	15
N-Acetylation	<i>N</i> -Acetyl transferase	Acetyl CoA	Aromatic hydrazines	Acetyl radical	Isoniazid	16

			Haloalkenes	Thioketene	Hexachlorobutadiene	21
			Benzoquinone	Bromohydroquinone-linked	Bromobenzene	22
				cysteine- <i>S</i> -conjugates		
			<i>o</i> -Quinone	<i>o</i> -Quinone-NAC adduct	Ecstasy	23,24
			<i>S</i> -Acyl-CoA	<i>S</i> -Acyl-GSH thioester	Clofibrilic acid	25
			Isothiocyanate	Carbamoyl–GSH	α -Naphthylisothio-cyanate	26
			Isocyanate	Thiocarbamoyl–GSH	Methyl isocyanate	27
<i>S</i> -Acyl-CoA formation	Acyl CoA synthetases	CoASH, ATP	Carboxylic acids	<i>S</i> -Acyl-CoA	Ibuprofen	28
				Acyl-AMP	Cholic acid	29

Abbreviations: UDP, uridine diphosphate; UDPGA, UDP- α -D-glucuronic acid; *N*-hydroxy-2-AAF, *N*-hydroxy-2-acetylaminofluorene; PAPS, 3'-phosphoadenosine-5'-phosphosulfate; 7-OH-DMBA, 7-hydroxymethyl-12-methylbenz[*a*]anthracene; *N*-hydroxy-MAB, *N*-hydroxy-4-methylaminobenzene; acetyl CoA, acetyl coenzyme A; NAC, *N*-acetylcysteine; GSH, glutathione; acyl-AMP, acyl-adenylate; CoASH, coenzyme A; ATP, adenosine triphosphate.

Conjugation of reactive intermediates with GSH with or without catalysis by GSH *S*-transferases (GST) is often important for their detoxification. However, in some cases, such as in the conjugation of GSH to haloalkanes, haloalkenes, and benzohydroquinones, it instead leads to the formation of reactive intermediates that covalently bind to protein and contribute to tissue toxicity [32]. Sometimes bioactivation of xenobiotics by GSH conjugation requires further metabolism via mercapturic acid pathway enzymes as well as renal cysteine β -lyase leading to chemically reactive, potentially toxic, intermediates [33].

Acyl-*S*-CoA synthetases are involved in the activation of carboxylic-acid-containing drugs to *S*-acyl-CoA thioesters that function as necessary substrates for certain phase II conjugating enzymes that lead to their detoxification, for example, in the formation of amino acid conjugates that are eliminated into urine. However, chemically reactive *S*-acyl-CoA thioesters are known to mediate the transacylation of protein nucleophiles and, therefore, similar to reactive acyl glucuronides, have been proposed to mediate idiosyncratic allergic toxicity for some acidic drugs [34].

Thus, both phase I and phase II classes of xenobiotic metabolism, as well as their combination, can function in the metabolic activation of xenobiotics leading to chemically reactive intermediates that bind covalently to DNA or tissue proteins potentially leading to subsequent organ toxicity. This chapter covers the metabolic mechanisms involved in the phase-II-mediated bioactivation of xenobiotics to reactive metabolites and their toxicological consequences.

4.3 GLUCURONIDATION

Metabolism by phase-II-mediated glucuronidation represents a major route of clearance of xenobiotics and/or xenobiotic metabolites from the body [35,36]. The conjugation reaction leading to the formation of glucuronide metabolites is catalyzed by two families (based on amino acid sequence similarity) of UGT enzymes (EC 2.4.1.17) UGT1 and UGT2, which are further divided into three subfamilies, UGT1A, UGT2A, and UGT2B. UGT enzymes are located in high concentration in liver tissue, but they are also found in other tissues such as kidney, heart, stomach, intestine, colon, esophagus, brain, adrenal glands, and thymus [37,38]. The ability of a certain tissue to metabolize a substrate by glucuronidation depends on the presence and concentration of the appropriate UGT isoforms in the tissue [39].

UGTs are membrane-bound enzymes, in which the subcellular location is in the smooth endoplasmic reticulum (microsomal fraction) [35]. The cofactor necessary for UGT function is UDP- α -D-glucuronic acid (UDPGA), which is derived initially from the catabolism of glycogen in the cytosol leading to the formation of glucose-1-phosphate. Further reaction with uridine triphosphate (via pyrophosphorylase) leads to the formation of UDP-glucose that is finally biotransformed to UDPGA by UDP-dehydrogenase.

Xenobiotics that are metabolized by glucuronidation have nucleophilic functional groups such as hydroxyls, carboxylic acids, amines, and reduced sulfhydryls, leading to the formation of ether-, acyl-, amino-, and thioether-linked glucuronides, respectively. The mechanism of glucuronide formation catalyzed by UGTs occurs whereby the "electron-rich" nucleophile of the substrate reacts in a nucleophilic displacement

Figure 4.1 Mechanism of β -D-glucuronide conjugate formation catalyzed by UGTs.

fashion with the C-1 position of the glucuronic acid ring of UDPGA to provide the β -D-glucuronide product (Fig. 4.1).

Glucuronidation of lipophilic xenobiotics and/or xenobiotic metabolite substrates, in most cases, leads to detoxification products that are chemically stable and have increased water solubility because of the high hydrophilicity of the glucuronic acid moiety, leading to their efficient excretion from the body in bile and/or urine [40]. Glucuronide conjugates of drugs can also be transported into bile and urine via efflux transporters (e.g., multidrug-resistance-associated protein 2) located in the hepatic bile canalicular and renal tubular brush border membranes [41–43]. Glucuronidation of endogenous compounds and xenobiotics sometimes results in the formation of glucuronide-linked metabolites that are pharmacologically more potent and/or toxic than their respective aglycones [30,44]. Thus, glucuronidation of drugs in most cases results in the loss of pharmacological activity, except in a few known cases where the glucuronide conjugate is sometimes more potent (bioactive) than the parent aglycone (e.g., morphine-6-*O*-glucuronide) [45].

In terms of mediating toxicity, the glucuronidation of some drugs or xenobiotics has been shown to lead to hepatic cholestasis; for example, the estrogen steroid glucuronide estradiol-17 β -D-glucuronide and the cholestatic agent lithocholate-3-*O*-glucuronide have been shown to produce cholestasis that is related to the activity and expression of Mrp2 [46–49]. In addition to the important role of UGTs in the phase-II-mediated detoxification of xenobiotics and endogenous compounds (e.g., bile acids), they can also metabolize varied types of functional groups to chemically reactive electrophiles that are proposed to mediate the toxicity of a number of chemicals via covalent binding to protein [50]. The different types of toxicities that are proposed to be mediated by chemically reactive glucuronide conjugates include hypersensitivity (e.g., hepatic, renal) [51], carcinogenesis (e.g., bladder) [52], and gastroenteropathy [53]. The types of electrophilic glucuronides that have been well studied include acyl glucuronides of carboxylic-acid-containing xenobiotics (Table 4.2) and endogenous compounds [34,54,55] and N- or N-*O*-linked glucuronides formed by glucuronidation of hydroxamic acids [17,56].

4.3.1 Acyl Glucuronidation

The conjugation of carboxylic-acid-containing compounds with glucuronic acid leading to the formation of 1- β -*O*-acyl glucuronides is an important route of metabolism

for endogenous compounds, drugs, and xenobiotics [35,36]. 1- β -*O*-Acyl glucuronides are chemically unstable and undergo both hydrolysis-mediated and acyl-migration-mediated degradation *in vitro* and *in vivo* [57]. During *in vitro* studies performed in buffer (pH 7.4–7.5, 37°C), authentic 1- β -*O*-acyl glucuronide derivatives biosynthesized from a range of carboxylic acids having varying substitution at the carbon atom adjacent to the carboxylic acid's carbonyl group showed that steric hindrance caused by bulky groups such as methyl (e.g., ibuprofen, clofibric acid) and propyl (valproic acid) led to increased stability (Table 4.2) [50,54,58,59]. The range of 1- β -*O*-acyl glucuronide degradation half-lives (apparent first order) is wide and can vary from 0.3 h as observed for the arylacetic-acid-type drug tolmetin to 3.3 h for ibuprofen, and up to 79 h for valproic acid. In addition, the instability of 1- β -*O*-acyl glucuronides can increase with electronic differences that lead to the carbonyl carbon of the acyl linkage being more electrophilic. For instance, the 20-fold difference between the degradation rates of the 1- β -*O*-acyl glucuronide of the benzoic-acid-containing drugs salicylic acid (1.3 h) and telmisartan (26 h) might be explained in part by the presence of the *o*-hydroxy group of salicylic acid that, unlike telmisartan, is able to hydrogen-bond to the carbonyl oxygen resulting in increased dipole moment of the carbonyl group of the acyl linkage. The presence of a heteroatom at the β -position, such as the oxygen atom present in phenoxyacetic acids, instead of a less electronegative carbon atom also results in increased degradation rates (shorter half-life) of the 1- β -*O*-acyl glucuronide. For example, the sixfold faster degradation rate of clofibric-acid-1- β -*O*-acyl glucuronide (7.3 h) than that of gemfibrozil-1- β -*O*-acyl glucuronide (44 h) is influenced by the placement of the oxygen atom present at the β -position versus the 6-position of these 2,2-dimethylalkanoic acid derivatives. One last notable structure–activity relationship with regard to 1- β -*O*-acyl glucuronide instability in buffer is for (*R*)- and (*S*)-2-phenylpropionic acid (2-PPA) 1- β -*O*-acyl glucuronides, where, owing to the α -methyl group in the (*S*)-isomer encumbering intramolecular acyl migration [60], the (*R*)-isomer degrades twofold more rapidly than the (*S*)-isomer [61].

Carboxylic-acid-containing compounds are proposed to form covalent adducts with proteins in fashion that is mediated by metabolism to chemically reactive acyl glucuronide derivatives [54,58,62]. In general, the chemical reactivity of acyl glucuronides with biological nucleophiles, such as albumin and other proteins, *in vitro* and *in vivo* decreases with increasing substitution at the carbon adjacent to the carbonyl carbon of the carboxylic acid moiety [54,63]. In experiments performed by Benet *et al.* [54], it was shown that the *in vitro* degradation rates of authentic 1- β -*O*-acyl glucuronides (due to both acyl migration and hydrolysis) of nine structurally varied carboxylic acid drugs correlated with their corresponding covalent binding to albumin *in vitro* and human plasma protein *in vivo*. Bolze *et al.* [63] demonstrated a similar correlation for eight structurally different carboxylic acid drug acyl glucuronides, where in one *in vitro* experiment, both the formation of acyl glucuronide metabolites by human liver microsomes and the assessment of corresponding reactivity with protein were achieved. A strong correlation was established between the maximal amount of covalently bound drug to protein (normalized to the amount of protein and expressed as percentage of total acyl glucuronide synthesized in the microsomal incubation) and the aglycone appearance rate constant weighted by the percentage of isomerization [63]. In general, structure–reactivity observations from these studies showed the rank

order of 1- β -*O*-acyl glucuronide instability and covalent binding to protein to be arylacetyl linked > 2-phenylpropionyl linked > benzoyl linked [54,63]. More recently, a novel quantitative LC/MS/MS technique was developed to study the reactivity of acyl glucuronide metabolites with protein by measuring the rate of reaction of structurally varied drug acyl migration isomers with the dipeptide lysine–phenylalanine (Lys–Phe) in buffer, leading to the formation of the corresponding acyl glucuronide–Lys–Phe Schiff-base-linked adducts [64]. It was proposed that the degree of reactivity of acyl glucuronides with protein would be proportional to the amount of the corresponding Lys–Phe adducts formed *in vitro*. In support of this proposal, results from their experiments showed a structure–reactivity relationship where the reaction rate rank order of forming the dipeptide adducts was acetic acid > propionic acid > benzoic acid derivatives, which was consistent with previous observations based on the steric and electronic properties of each carboxylic acid tested [54,64].

Carboxylic-acid-drug-protein adducts are hypothesized to function as immunogenic complexes that are recognized by the immune system as foreign leading to immunotoxic reactions [50,51]. The irreversible binding to albumin *in vivo* was shown in bilirubin-1- β -*O*-acyl glucuronide, leading to the formation of biliprotein as one of the first reports on acyl glucuronide-mediated covalent binding to protein [65]. Since that report, *in vitro* studies have shown that 1- β -*O*-acyl glucuronide conjugates of carboxylic acid drugs, for example, zomepirac [66], tolmetin [67], and benoxaprofen (BNX), also bind covalently to protein. Observations from mechanistic studies such as these indicated that 1- β -*O*-acyl glucuronides covalently bind to protein by two alternative reaction mechanisms (Fig. 4.2). One mechanism takes place where the electrophilic carbonyl carbon of the 1- β -*O*-acyl linkage of the acyl glucuronide reacts with protein nucleophiles (e.g., lysinyl-NH₂, tyrosine-OH and serine-OH, and cysteinyl-SH) via nucleophilic displacement of glucuronic acid leading to drug-amide-, ester-, and thioester-linked protein adducts, respectively (Fig. 4.2a). The second mechanism follows a more complex reaction route, where the 1- β -*O*-acyl glucuronide first undergoes acyl migration from 1- β -*O*-acyl position to the adjacent hydroxyl group around the glucuronic acid ring forming 2-, 3-, and 4-*O*-acyl migration isomers (Fig. 4.2b) [68]. Unlike 1- β -*O*-acyl-linked glucuronides, the acyl migration isomers are not hydrolyzed by the enzyme β -glucuronidase [69]. These acyl migration isomers in the ring tautomer form are in equilibrium with their corresponding open-chain tautomers, which are aldehydes that can react with the ϵ -amino groups of protein–lysiny residues forming Schiff-base-linked protein adducts. The 3- and 4-*O*-acyl glucuronide Schiff-base-linked adducts can then undergo a stabilization reaction via an Amadori rearrangement yielding stable 1-amino-2-keto-linked acyl glucuronide protein adducts [66,70]. The covalent products formed from these two pathways are significantly different in that, unlike the transacylated nucleophilic displacement product, the Schiff base mechanism of covalent binding leads to protein adducts that retain the glucuronic acid moiety. Such a common moiety linking proteins to drugs might function as a common neoantigen and serve as an explanation for cross-reactive allergic reactions between structurally varied nonsteroidal anti-inflammatory drugs (NSAIDs) [50,71]. From these observations, it was proposed that there may be a relationship between the *in vivo* covalent binding of acyl glucuronide metabolites of acidic drugs to protein and toxicological properties of the drugs [54,58,61,66]; however, convincing data to support this proposal is still lacking.

Figure 4.2 Mechanisms for (a) the transacylation of protein nucleophiles by 1-β-O-acyl-linked glucuronides and (b) stable adduct formation with lysine residues on proteins by acyl glucuronide migration isomers.

A total of 17 carboxylic-acid-containing drugs were withdrawn from the worldwide pharmaceutical market during 1960–1999 for safety reasons, including hepatotoxicity, renal failure, and/or dermatologic toxicity [72]. Some of these drugs included the 2-arylpropionic acid (profen) NSAIDs BNX, indoprofen, and suprofen; the arylacetic acid NSAIDs bromfenac, fenclofenac, ibufenac, and zomepirac; and the benzoic-acid-containing anti-infective quinolone drugs temafloxacin and trovafloxacin (Table 4.2). These drugs are biotransformed to varying extents to 1-β-O-acyl glucuronide metabolites [73–80]. In addition to these withdrawn drugs, currently used drugs that are also metabolized by acyl glucuronidation and have been characterized for covalent binding properties include diclofenac [71], diflunisal [81], valproic acid [82], tolmetin [83], clofibric acid [84], ibuprofen [85], and salicylic acid [86] (structures shown in Table 4.2).

4.3.1.1 Benoxaprofen. The NSAID BNX (2-[2-(4-chlorophenyl)-1,3-benzoxazol-5-yl]propanoic acid) was withdrawn from clinical use in 1982 when it was determined to mediate a rare but fatal cholestatic jaundice [87,88]. The mechanism of hepatotoxicity remains unexplained, but it has been postulated that the hepatotoxicity could be related to the formation of BNX–protein covalent adducts formed via a reactive acyl

glucuronide metabolite in the liver. However, no indication of immune-mediated hepatotoxicity was ever observed in BNX-treated patients. BNX-1- β -*O*-acyl glucuronide is the major metabolite (90% of the dose) of BNX formed in humans, and two-thirds of the acyl glucuronide was reported to be renally excreted, with the remaining amount eliminated in feces [89].

Tandem mass spectrometry was used to identify the mechanism of covalent binding to protein formed during incubations of with human serum albumin (HSA) [90]. Results demonstrated that BNX-1- β -*O*-acyl glucuronide mediated the formation of covalent adducts with protein nucleophiles on HSA by both nucleophilic displacement and Schiff base reactions with Lys-159 and Lys-199 ϵ -amino-lysine residues, where Lys-159 was identified as the major amino acid involved in BNX-protein adduct formation. Similar results were obtained from studies with tolmetin-1- β -*O*-acyl glucuronide, where covalent binding to HSA by both transacylation and Schiff base mechanisms was also detected; however, Lys-199 was determined to be the major site of tolmetin-protein adduct formation [67]. Other major binding sites of transacylation by BNX-1- β -*O*-acyl glucuronide included Ser-312, Ser-480, and Arg-222.

In vivo covalent binding studies in rat showed BNX to become irreversibly bound to plasma and liver proteins, and immunochemical techniques detected the presence of multiple hepatic protein targets [91]. Results showed the formation of protein adducts with masses of 70 and 110 kDa as the primary hepatic targets. *In vitro* covalent binding of BNX-1- β -*O*-acyl glucuronide (170 μ M) to HSA (30 mg/mL, pH 7.4, 37°C) was time dependent and reached 45 pmol/mg protein after 24 h of incubation. The apparent first-order degradation half-life of the acyl glucuronide during incubation was 1.55 h, compared to 1.43 h in buffer alone. No covalent binding was detected in corresponding incubations with BNX-free acid. The formation of BNX-protein adducts in rat hepatocyte cultures, which were depleted of UDPGA (by treatment with [–]-borneol), led to a 46% inhibition in protein adduct formation as detected by SDS-PAGE Western immunoblotting analysis. The partial inhibition of covalent binding to protein suggested that other bioactivation mechanisms must also be involved. Other routes of BNX bioactivation leading to covalent binding to protein in the liver might include P450-mediated oxidation, acyl glucuronidation, and/or *S*-acyl-CoA formation (discussed below). BNX contains a benzoxazole substructure potentially able to be metabolized via phase I metabolism to reactive intermediates that could account for, at least in part, some of the covalent binding to hepatic protein occurring *in vivo*. However, in a recent report, the covalent binding of [¹⁴C]BNX to protein in NADPH-fortified human liver microsomes also showed no detectable covalent binding to protein [92]. These results suggest that BNX is not biotransformed by cytochrome P450 to reactive intermediates (e.g., epoxides), and no GSH conjugates of BNX have been reported to date. In another study, BNX-1- β -*O*-acyl glucuronide formation was shown not to be a critical protein-reactive intermediate of BNX because *in vitro* experiments conducted in UDPGA-fortified human liver S-9 fraction appeared to completely block covalent binding of BNX to protein [93]. To date, evidence for the causative reactive metabolite(s) of BNX leading to hepatic cholestasis is not available. One proposal put forward is that an insoluble metabolite of BNX leads to drug-related precipitation in the bile canaliculi as the mechanism of cholestasis [88]; however, an insoluble metabolite of BNX has never been observed. Other studies in sandwich-cultured rat and human hepatocytes have demonstrated both BNX glucuronidation and BNX covalent binding to protein [94]. From those studies, it was proposed that sandwich-cultured human hepatocytes

be used as an *in vitro* tool to investigate the role of acyl glucuronidation in the covalent binding of other acidic drugs to protein as a screening method, but perhaps, the method could also be employed to investigate further the mechanism of BNX-mediated cholestatic hepatotoxicity [95].

4.3.1.2 Diclofenac. Diclofenac (2-[2-(2,6-dichlorophenyl)-aminophenyl]ethanoic acid) is an NSAID used clinically for the treatment of patients with osteoarthritis, rheumatoid arthritis, ankylosing spondylitis, and acute muscle pain [96]. Diclofenac has been implicated in several cases of severe idiosyncratic hepatotoxicity as well as enteropathy, hemolytic anemia, and immune-mediated anaphylaxis [97]. One proposed molecular mechanism mediating diclofenac-induced hepatitis is that reactive metabolites of diclofenac covalently bind to protein and are then recognized by the immune system as foreign, thus leading to an immunotoxic response [10,98]. Diclofenac is metabolized by UGT2B7 in humans and UGT2B1 in rats where 10–20% of the drug is eliminated as the acyl glucuronide [99]. The apparent first-order degradation half-life of diclofenac-1- β -*O*-acyl glucuronide (D-1- β -*O*-G) in buffer at pH 7.4 and 37°C is rapid (0.51 h), and D-1- β -*O*-G degrades primarily via acyl migration [58]. Other *in vitro* studies conducted in buffer showed that D-1- β -*O*-G is chemically reactive and transacylates GSH forming diclofenac-*S*-acyl-GSH [100]. In studies where diclofenac was incubated with rat and human hepatocytes, diclofenac-*S*-acyl-GSH thioester was also formed. However, the GSH thioester formation was not mediated by D-1- β -*O*-G because inhibition of D-1- β -*O*-G production had no effect on diclofenac-*S*-acyl-GSH formation. These results suggested that diclofenac must also be biotransformed to chemically reactive metabolites other than D-1- β -*O*-G, leading to the transacylation of GSH. Covalent binding studies performed in short-term-cultured rat hepatocytes showed diclofenac acyl glucuronide formation to be associated with covalent binding of the drug to hepatocellular proteins; however, this was not related to the acute cytotoxicity [101]. From these studies, it was proposed that protein adduct formation, and its modulation by UDPGT, can be toxicologically important for the formation of diclofenac-induced hepatitis. Further studies conducted *in vivo* in rat and *in vitro* in short-term-cultured rat hepatocytes showed that covalent binding of diclofenac to hepatocyte proteins is selective, where a 60-kDa microsomal membrane protein appeared to be the major target for covalent binding in rat liver and in the cultured hepatocytes exposed to diclofenac [102]. The covalent binding of diclofenac to protein was investigated in incubations with rat liver microsomes and was shown to be time dependent and UDPGA cofactor dependent. In addition, diclofenac covalent binding to protein was significantly increased in the presence of the imine-trapping reagent, sodium cyanide, and was significantly decreased by 7,7,7-triphenylheptyl-UDP, a specific inhibitor of UGT. Covalent binding to protein resulted in an adduct weighing 60 kDa. Overall, the results indicated that diclofenac acyl glucuronide covalently binds to hepatic microsomal proteins by both nucleophilic displacement and Schiff base mechanisms [71]. *In vivo* covalent binding studies with diclofenac in rat, using immunoblotting techniques, led to the detection of a diclofenac-labeled 50-kDa rat liver microsomal protein (P450 mediated) and 110-, 140-, and 200-kDa diclofenac-adducted plasma membrane proteins (UGT mediated) [103].

The 110-kDa diclofenac-labeled protein adduct in rat liver was later determined to be dipeptidyl peptidase IV (CD26), and it was found that the activity of CD26 in liver plasma membrane fractions was decreased after diclofenac treatment of rats. It was

proposed that the hepatotoxicity associated with diclofenac might be due, at least in part, to the covalent modification of CD26 [104]. More recently, studies on the covalent binding of diclofenac to protein in normal Wistar rats compared to that occurring in mutant transport-deficient (TR⁻) rats demonstrated that diclofenac glucuronide is selectively transported into rat bile mediated by Mrp2 and that hepatobiliary transport is necessary for diclofenac covalent binding to protein (118-kDa canalicular protein detected as the major protein adduct) in the biliary tree [105].

Results from one study showed the formation of IgM autoantibodies against the acyl glucuronide conjugate of 4'-hydroxydiclofenac that was detected in the urine of a diclofenac-dosed patient suffering from acute Coombs-positive hemolytic anemia [106]. The metabolite was shown to promote agglutination of normal red blood cells and therefore was proposed to potentially mediate hemolytic anemia. The 4'-hydroxydiclofenac acyl glucuronide was determined to be catalyzed by CYP2C8-mediated metabolism of D-1- β -O-G [107]. Along a similar line, gemfibrozil-1-O-acyl glucuronide has been shown to be bioactivated by CYP2C8-mediated hydroxylation leading to reactive metabolite formation and subsequent time-dependent inactivation of the enzyme [108,109].

The small intestinal injury caused by diclofenac has been proposed to occur by enterocyte cytotoxicity mediated by the reactive acyl glucuronide of diclofenac or the acyl glucuronide of one of its oxidative metabolites [110]. In one study, post administration of diclofenac to rats by gastric gavage, subsequent immunoblotting analysis of small intestine homogenates and isolated enterocyte subcellular fractions with drug-specific antiserum revealed 142-, 130-, 110-, and 55-kDa protein adducts [111]. The 142- and 130-kDa protein adducts of diclofenac were identified as aminopeptidase N (CD13) and sucrase-isomaltase, respectively. These authors proposed that oral tolerance to intestinal drug-protein adducts can be developed in gut-associated lymphoid tissue, leading to the downregulation of drug-induced allergic reactions in many individuals who do not have gut toxicity to diclofenac.

Diclofenac also undergoes cytochrome P450C9- and 3A4-mediated oxidation of the aromatic ring to 4'- and 5-hydroxylated products, respectively. These hydroxylated metabolites then can undergo further P450-mediated oxidation to electrophilic quinone imine metabolites that react, in a Michael acceptor fashion, with GSH and proteins [112,113]. Other mechanisms propose diclofenac-mediated cytotoxicity to be caused by mitochondrial damage, P450-mediated reactive metabolites, or oxidative stress induced by free-radical-containing metabolites [114–116]. In cytotoxicity studies with diclofenac conducted in rat hepatocytes, it was demonstrated that when diclofenac glucuronidation was inhibited with (–)-borneol, the LD₅₀ decreased from 1000 μ M in the absence of the inhibitor to 740 μ M in its presence [117], which was consistent with the results obtained by Kretz-Rommel and Boelsterli [101], where diclofenac was shown to cause P450-mediated acute cell injury in cultured rat hepatocytes. To date, clear evidence for the identity of causative hepatotoxic metabolite(s) (i.e., UGT- or P450-mediated) of diclofenac has not been obtained [98].

4.3.2 Glucuronidation of Arylhydroxamic Acids

Arylhydroxamic acids are metabolic products formed from the P450-mediated oxidative metabolism of N-acetylated N-arylamine-containing compounds, leading to a hydroxyl

Figure 4.3 Mechanisms by which *N*-hydroxy-2-AAF can lead to DNA adduct formation via *N*-O-glucuronidation or *N*-O-sulfonation.

group attached to the nitrogen of the acetyl-amino linkage. Glucuronidation of arylhydroxamic acids forming *N*-O-linked glucuronides was discovered as the first example of chemically reactive glucuronide metabolites [11,30,118].

4.3.2.1 2-Acetylaminofluorene. From early studies performed in the 1960s on the *in vivo* metabolism of the carcinogen 2-acetylaminofluorene (2-AAF), it was shown that a major metabolite eliminated in the urine of test animals was the O-linked glucuronide of *N*-hydroxy-2-AAF (Fig. 4.3) [119]. The specific rat UGT isoforms known to catalyze O-linked glucuronide formation of *N*-hydroxy-2-AAF include UGT2B1, UGT2B2, and UGT1A6 [120]. Recombinant human UGT isoforms expressed in liver that catalyze the glucuronidation were shown to be UGT1A6 and UGT2B7 [121]. Therefore, in rats and rabbits, 2-AAF had undergone P450-mediated *N*-hydroxylation followed by O-glucuronidation before urinary elimination. The glucuronide was determined to be degradable by treatment with β -glucuronidase.

Later it was shown that the O-linked glucuronide of *N*-hydroxy-2-AAF was chemically reactive *in vitro* at pH 7 with the amino acids methionine and tryptophan as well as with the *N*²-position of the purine nucleoside guanosine forming products, where the acetyl group was retained [11]. The mechanism by which the *N*-O-glucuronide of *N*-hydroxy-2-AAF leads to adduct formation with nucleophiles is believed to proceed by the *N*-O-glucuronide undergoing heterolytic decomposition to DNA-reactive *N*-acetyl-*N*-aryl-nitrenium or carbonium ions (Fig. 4.3) [17]. Comparisons of the chemical reactivity of the *N*-O-glucuronide with the corresponding phosphate and sulfate *O*-esters (discussed below) of *N*-hydroxy-2-AAF showed lower reactivity for the glucuronide [52,122]. However, the chemical reactivity of the *N*-O-glucuronide of *N*-hydroxy-2-AAF was enhanced in incubations performed at higher pH, leading to increased adduct detection [123], which may be toxicologically significant, for instance, in bladder cancer when urinary pH is elevated [17,44]. The *N*-O-glucuronide of *N*-hydroxy-2-AAF in buffer under mildly basic pH conditions undergoes deacetylation to form the substantially more reactive electrophile *N*-hydroxy-2-aminofluorene *O*-glucuronide [17,124,125]. Structure–reactivity relationship experiments for *O*-glucuronides of *N*-acetyl-*N*-arylhydroxylamines in reactions with nucleic acids showed that the rank order of reactivity with respect to the aryl group being 2-AAF > *trans*-4-acetamidostilbene > 4-acetamidophenyl > 2-acetamidophenanthrene [126].

There is no evidence for the direct UGT-catalyzed glucuronidation of *N*-O-glucuronides of arylhydroxylamines (potentially due to their high instability), where their biological formation depends instead on the degradation of N–O-linked glucuronides of *N*-acetyl-*N*-arylhydroxylamines [30]. However, the UGT-mediated biosynthesis of N-linked glucuronides of both arylamines and arylhydroxylamines does occur, but in these cases, the product *N*-glucuronides are not perceived to be toxicologically important since they otherwise do not readily generate reactive electrophiles [17]. However, under acidic conditions (pH 5), N-linked glucuronides of *N*-arylhydroxylamines (e.g., *N*-hydroxy-2-naphthylamine) are labile and might serve as proximate carcinogens before acid-catalyzed degradation, eventually leading to highly reactive arylnitrenium ions [17,127].

In summary, *O*-glucuronide conjugates of *N*-acetyl-*N*-arylhydroxylamines may play an important role in the extrahepatic tissues' carcinogenicity induced by N-acetylated *N*-arylamines such as 2-AAF by serving as relatively stable transport species of P450-mediated N-hydroxylated precursors. In nonhepatic target organs such as the bladder, N–O-linked glucuronides can then undergo pH-dependent hydrolytic reactions to liberate chemically reactive metabolites [17,128].

In studies conducted by King and Phillips [122], they demonstrated a 105,000g supernatant protein fraction of rat liver to catalyze covalent reactions of 2-AAF with nucleic acid, and the cofactor requirements suggested, in part, that the reactive intermediates involved were the *O*-sulfonate esters (discussed below) of *N*-hydroxy-2-AAF. Sulfonate esters have been established as ultimate carcinogens in 2-AAF-induced hepatocarcinogenesis, where interspecies comparisons for tumor incidence were consistent with *O*-sulfonate ester formation [129]. The *O*-glucuronide-linked metabolites of *N*-acetyl-*N*-arylhydroxylamines have been proposed to be stable transport forms of carcinogens and as such determine the target organ of toxicity, for example, in 2-AAF-induced bladder carcinogenesis [130].

Figure 4.4 Mechanism of *O*-sulfonate conjugate formation catalyzed by SULTs.

4.4 SULFONATION

Sulfonation of a wide range of structurally varied endogenous compounds, drugs, and other xenobiotics by cytosolic SULT (EC 2.8.2) enzymes most often represents an important route of their clearance and detoxification from the body [131–133]. SULT enzymes catalyze the conjugation of a sulfonate group (SO_3^-) from the endogenous universal donor 3'-phosphoadenosine-5'-phosphosulfate (PAPS) to hydroxyl, amino, or sulfhydryl groups of substrates forming sulfonates, sulfamates, and thiosulfates, respectively (Fig. 4.4) [31,131,134]. Sulfonation of a substrate hydroxyl group to produce sulfonate is the most common sulfonation reaction observed in the body [135]. The SULT cofactor PAPS is biosynthesized from SO_4^{2-} obtained from the amino acids cysteine and methionine, and two molecules of ATP are necessary for the synthesis of each PAPS molecule produced. PAPS is present in low concentrations in the cytosol, and therefore, the sulfonation pathway may be saturated at high substrate concentrations. The sulfonate group ($\text{p}K_a < 1$) is ionized at physiological pH such that the sulfate-containing conjugates are often water soluble and in most cases are incapable of binding and activating their corresponding receptors compared to their unconjugated parent molecules [31,135]. However, there are examples of drugs that undergo sulfonation leading to sulfate ester metabolites that are more pharmacologically potent than their parent drugs. Such examples include the vasodilator minoxidil [136,137] and the antihypertensive agent cicletanine [138].

Generally, conjugation of xenobiotics with a sulfonate group results in increased water solubility leading to their efficient excretion from the body into urine and/or bile. For example, *O*-sulfonation is required for detoxification and elimination of drugs such as acetaminophen (APAP), which is a leading cause of liver failure in humans [139,140]. However, *O*-sulfonation is also increasingly being shown to function as a bioactivation mechanism for promutagens and procarcinogens by leading to the formation of chemically reactive electrophiles that bind covalently to DNA, RNA, and protein nucleophiles [9,31,122,141].

SULTs have a wide tissue distribution and function as a major detoxification mechanism in adults and in the developing human fetus [142]. Two broad classes of SULTs are known. One class is membrane bound and is located in the Golgi apparatus, which

functions in the sulfonation of endogenous peptides, proteins, carbohydrates, and lipids. The second class of SULTs is soluble and is located in the cytosol where it is known to mediate the metabolism of steroids, neurotransmitters, bile acids, and xenobiotics [135,142]. Therefore, the cytosolic SULTs are the important class of SULT enzymes relevant to xenobiotics metabolism, disposition, and potential bioactivation. A nomenclature system for the cytosolic SULT superfamily has been developed [143], and at least 13 human SULTs that differ strongly in their tissue distribution and their substrate specificity have been characterized [31,142]. There are two main SULT families that are known to mediate mutagenicity and carcinogenicity by metabolism of phenolic and arylhydroxylamine-containing xenobiotics. These families include the aryl (phenol) SULTs (aryl-SULT, SULT1; EC 2.8.2.1) and alcohol (hydroxysteroid) SULTs (alcohol-SULT, SULT2; EC 2.8.2.2) [31,141].

Discussed below are some known examples of xenobiotic chemical classes that undergo metabolic activation by SULTs, including polycyclic aromatic benzylic alcohols, allylic alcohols, *N*-arylhydroxylamines, and *N*-acetyl-*N*-arylhydroxylamines.

4.4.1 Polycyclic Aromatic Benzylic Alcohols

Benzylic-*O*-hydroxy metabolites of methyl-substituted polycyclic hydrocarbons can undergo sulfonation to form extremely reactive sulfonate esters that play a role as ultimate mutagens and/or carcinogens.

4.4.1.1 7-Hydroxymethyl-12-methylbenz[*a*]anthracene. Studies have shown that benzylic-*O*-hydroxy polycyclic hydrocarbons such as 7-hydroxymethyl-12-methylbenz[*a*]anthracene (7-OH-DMBA) are bioactivated preferentially by hepatic hydroxysteroid SULT to unstable benzylic sulfonate esters that degrade to highly reactive benzylic carbocations that covalently bind to DNA, RNA, and proteins (Fig. 4.5) [12,144,145]. 7,12-Dimethylbenz[*a*]anthracene (DMBA) is a polycyclic aromatic compound determined to be a potent carcinogen. DMBA is found in the environment and produced from the incomplete combustion of organic matter.

7-OH-DMBA is a carcinogenic major metabolite of DMBA formed in the liver [144]. *In vitro* studies with 7-OH-HMBA showed that covalent binding to DNA was observed during incubations with human liver cytosol and only when fortified with PAPS [145]. Similar results were obtained with the hydroxylated DMBA metabolites 7-methyl-12-hydroxymethylbenz[*a*]anthracene (12-OH-DMBA) and 7,12-dihydroxymethylbenz[*a*]anthracene (7,12-diOH-DMBA). Results from studies also showed that the SULT-mediated activation of the methyl-hydroxylated DMBA derivatives was predominantly catalyzed by dehydroepiandrosterone DHEA-steroid SULT. Further studies showed that GST-mediated detoxification, with GSH forming the nonmutagenic *S*-(12-hydroxymethylbenz[*a*]anthracen-7-yl)methyl-GSH product, occurred during incubations of 7,12-diOH-DMBA with PAPS and GSH-supplemented hepatic cytosol, where the GSH adduct was formed directly from DHBA-7-sulfate as the obligatory intermediate [12]. Results from studies such as these strongly support the hypothesis that polycyclic-aromatic-type benzylic alcohols undergo SULT-mediated bioactivation related to the formation of DNA adducts. In addition to the bioactivation of primary benzylic alcohols as discussed above, secondary benzylic alcohols (e.g., 1-hydroxy-3-methylcholanthrene) [146] can also undergo bioactivation by SULTs leading to the formation of chemically unstable mutagenic/carcinogenic sulfonate metabolites.

Figure 4.5 Metabolic activation of benzylic and allylic alcohols leading to the formation of unstable sulfonate esters that decompose forming benzylic and allylic carbocations capable of covalently binding to DNA.

4.4.2 Allylic Alcohols (Tamoxifen)

The nonsteroidal antiestrogen drug tamoxifen (TAM) is used as a long-term chemopreventative for breast cancer in healthy women [147]. The drug has been shown to be a potent genotoxic hepatocarcinogen in rats [148], and the increased risk, however rare, of endometrial cancer in long-term TAM-treated breast cancer patients has heightened concerns about the use of the drug [149].

DNA adducts of TAM have been observed in both rat and human tissues, and the hepatocarcinogenic effects in rat are known to follow a mechanism where DNA adducts accumulate in the liver. The pathway of bioactivation of TMA leading to DNA adduct

formation is sequential and involves cytochrome P450-mediated α -hydroxylation followed by O-sulfonation leading to an unstable sulfonate ester that decomposes to a highly reactive allylic carbocation that binds covalently to DNA (Fig. 4.5) [13].

Multiple human P450s, including P450 3A4 and, to a lesser extent, P450 2D6, P450 2B6, P450 3A5, P450 2C9, and P450 2C19, have been shown to mediate the formation of α -hydroxy-TAM [150]. Many of these P450s are found in endometrial tissue and therefore may mediate the production of reactive metabolites that play a role in the formation of endometrial cancer. The formation of α -hydroxy-TAM-sulfonate from α -hydroxy-TAM has been shown to be catalyzed by both rat liver hydroxysteroid (alcohol) SULT-a and human alcohol (hydroxysteroid) SULT enzymes (SULT2A1) [151,152]. The production of TMA-DNA adducts is known to occur during incubations of TAM with both rat and human hepatocytes [153,154]. However, TAM-DNA adduct formation occurs to a less extent in incubations with human hepatocytes than that measured in rat hepatocytes. This observation has been explained by a lower extent of TAM bioactivation (by α -hydroxylation or sulfonation) and a greater rate of glucuronidation-mediated detoxification of α -hydroxy-TAM occurring in human compared to rat.

Other mutagenic/carcinogenic allylic alcohols that are well known to be metabolically activated by SULTs include 1'-hydroxysafrole, 1'-hydroxyestragole, 5-hydroxymethylfural, and α -hydroxycyproterone acetate [141].

4.4.3 Arylhydroxylamines and Arylhydroxamic Acids

4.4.3.1 4-Dimethylaminobenzene. 4-Dimethylaminobenzene (DAB) is a hepatocarcinogenic dye that was used as an industrial chemical and shown to induce the formation of liver tumors in rat [155]. DAB undergoes sequential metabolism via cytochrome P450 by N-demethylation to 4-methylaminobenzene (MAB), followed by flavoprotein mixed-function amine-oxidase-mediated N-oxidation to the arylhydroxylamine, *N*-hydroxy-MAB [156]. Incubations of *N*-hydroxy-MAB with rat liver cytosol fortified with PAPS led to the production of adducts of methionine, guanosine, ribosomal RNA, and GSH [14,157]. The formation of these adducts was dependent on the O-sulfonation of *N*-hydroxy-MAB to the product sulfonate ester, which decomposes to a chemically reactive electrophilic nitrenium ion and sulfate (Fig. 4.6). Some other carcinogenic *N*-arylhydroxylamines that are known to be metabolically activated by human liver thermostable phenol SULTs include *N*-hydroxy derivatives of 2-aminofluorene, 4,4'-methylene-bis(2-chloroaniline), 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine, and 2-amino-6-methyldipyrido[1,2-*a*:3',2'-*d*]imidazole [158]. The thermostable phenol SULT (SULT1A1) appears to be polymorphically expressed in humans. Therefore, an important role for the enzyme has been suggested to be related to interindividual susceptibility to *N*-arylhydroxylamine-containing carcinogens [158,159].

4.4.3.2 2-Acetylaminofluorene. As discussed above, the carcinogenic N-acetylated *N*-arylamine 2-AAF is bioactivated by P450-mediated N-hydroxylation followed by O-glucuronidation leading to the unstable N-O-linked glucuronide that decomposes to the chemically reactive nitrenium ion. In addition to this metabolic activation route, *N*-hydroxy-2-AAF undergoes O-sulfonation-mediated bioactivation to an unstable O-sulfonate ester (Fig. 4.3). Just as described above for the O-sulfonate ester of

Figure 4.6 Metabolic activation of 4-dimethylaminobenzene (DAB) leading to a chemically reactive electrophilic nitrenium ion that covalently binds to DNA.

N-hydroxy-MAB, the *O*-sulfonate ester of *N*-hydroxy-2-AAF undergoes heterolytic cleavage to the electrophilic *N*-acetyl-*N*-aryl-nitrenium ion [15]. The nitrenium ion is in resonance with the aryl carbocations that also contribute to the formation of covalent adducts with DNA nucleophiles [17]. Covalent binding to DNA by this mechanism was shown to lead to the formation of 3-deoxyguanosin- N^2 -yl-2-AAF and *N*-deoxyguanosine-8-yl-2-AAF adducts [141,160]. Similar to the hepatocarcinogenic affects of arylhydroxylamines, the metabolism of *N*-hydroxy-AAF by deacetylation to *N*-hydroxy-2-aminofluorene (*N*-hydroxy-AF) has been proposed as a critical bioactivation process leading to the formation of hepatic DNA adducts and the initiation of liver tumors in 12-day-old male B6C3F1 mice [161]. In those studies, it was shown that deacetylation of *N*-hydroxy-AAF to *N*-hydroxy-AF followed by *O*-sulfonation was essential for the leading to *N*-deoxyguanosine-8-yl-2-AF DNA adduct formation

and liver tumor initiation in infant male B6C3F1 mice treated with *N*-hydroxy-AAF [160].

In summary, the observations from the mechanistic studies with 2-AAF and related arylamines that were initially conducted in the 1950s by Miller and Miller and others led to a working hypothesis stating that for some compounds to become carcinogenic, they must first be metabolically activated by cytochrome P450 followed by O-conjugation forming unstable *O*-glucuronides and/or *O*-sulfonates, which lead to the formation of chemically reactive nitrenium ion or carbocation species that covalently bind to and damage DNA [9,162]. The irreversible interactions of these electrophilic metabolites with DNA, and the carcinogenic and mutagenic effects that occur with the resulting DNA damage, have provided the foundation on which much of the current mechanistic drug metabolism has been built and for genetic toxicity testing [163–166].

4.5 N-ACETYLATION

Conjugation of amines by N-acetylation, which is catalyzed by human NAT enzymes (EC 2.3.1.5) located primarily in the cytosol of the liver and many other tissues, plays an important role in the metabolism of drugs, xenobiotics and environmental chemicals and in both the detoxification and bioactivation of procarcinogens in humans [2,167–169]. The NAT enzyme reaction mechanism requires acetyl coenzyme A (acetyl CoA) as the cofactor to provide the acetyl group for the conjugation of aromatic amines or aromatic hydrazines forming aromatic amide or aromatic hydrazide metabolites, respectively (Fig. 4.7) [170]. The xenobiotic-metabolizing enzymes that are important in humans leading to the N-acetylation of drugs are NAT1 and NAT2, and the genetic polymorphisms for both enzymes are known, for example, the “slow” and “fast” acetylators of isoniazid [171,172]. The expression of NAT1 and NAT2 in humans differs, where NAT1 is widely expressed in varied tissues and NAT2 shows expression primarily in the liver and intestine.

Figure 4.7 Mechanism of N-acetylated amine formation catalyzed by NAT.

Figure 4.8 Metabolic activation of isoniazid initiated by N-acetylation, leading to the formation of reactive acetyl radical that covalently binds to protein.

The N-acetylation of xenobiotic-containing aromatic hydrazine (e.g., isoniazid) and aromatic amine (e.g., benzidine) functional groups can serve as a preliminary step in their bioactivation to chemically reactive intermediates that are proposed to induce hepatotoxicity or carcinogenesis by covalently binding to protein or DNA, respectively [17,173].

4.5.1 Aromatic Hydrazines—Isoniazid N-Acetylation

Isoniazid (isonicotinohydrazine, INH; Fig. 4.8), an aromatic-hydrazine-containing compound, is the primary drug used for the prevention and treatment of tuberculosis. INH causes hepatitis as one of its two major adverse toxicities and peripheral neuropathy is the other major toxicity. There is no clear evidence that INH-induced hepatotoxicity is immune mediated [174]. INH is metabolized primarily in the liver by NAT2-mediated N-acetylation to *N*-acetylisoniazid, where the rate of acetylation is genetically determined. Genetic polymorphisms of NAT2 correlate with fast-, slow-, and intermediate-acetylation phenotypes [175,176].

The proposed mechanism of bioactivation follows on such that *N*-acetylisoniazid is hydrolyzed to *N*-acetylhydrazine and isonicotinic acid. *N*-Acetylhydrazine then undergoes further oxidative metabolism by P450 enzymes to a highly reactive acylating acetyl radical species (Fig. 4.8) [16]. It was shown that covalent binding of this reactive species to hepatic macromolecules paralleled hepatocellular necrosis [177]. The trapped *S*-acetyl-GSH adduct has been detected from *in vitro* incubations [16]. Cytochrome P450 2E1 (CYP2E1) was shown to be important in the metabolic activation of *N*-acetylhydrazine, and CYP2E1 genetic polymorphism has been proposed to be associated with susceptibility to INH-induced hepatitis [178]. Recently, it was shown that CYP2E1 c1/c1 homozygotes are prone to developing more severe hepatotoxicity than other c1/c2 and c2/c2 genotypes [179]. Fast and slow acetylators excrete 90% and 60% of INH, respectively, as *N*-acetylisoniazid in urine; however, the effect of acetylation rate on isoniazid hepatotoxicity remains controversial [180].

4.5.2 Aromatic Amines—Benzidine

Aromatic-amine-containing carcinogens are metabolized by N-acetylation catalyzed by both human NAT1 and NAT2 enzymes [168]. N-Acetylation functions as a detoxification route of aromatic amines and as an alternative metabolic pathway to them undergoing CYP-mediated N-hydroxylation [181]. N-Hydroxylation of some aromatic amines is the first step toward their bioactivation leading to DNA-reactive electrophiles. Therefore, aromatic amines that may be inefficiently acetylated, because they are poor substrates for NAT and/or because of the slow acetylator phenotype, might “build up” and serve as substrates for oxidative enzymes such as CYP1A2 [182] leading to *N*-hydroxyaromatic amine (hydroxylamine) products, which become substrates for NAT enzymes leading to unstable aromatic *N*-acetoxyaromatic amine intermediates. *N*-Acetoxyaromatic amines are extremely reactive electrophiles that react with endogenous nucleophiles such as amino acids, proteins, RNA, and DNA [17]. Aromatic amines such as the bicyclic aromatic amine benzidine (4,4'-diaminobiphenyl), a formerly used chemical for the production of azo dyes [183], have been recognized as potential human carcinogens for many years [184]. One mechanism for the metabolic activation of benzidine that requires the participation of NAT follows on such that an initial CYP-mediated N-hydroxylation of benzidine followed by N-acetylation of the same N-hydroxylated nitrogen leads to an *N*-arylhydroxamic acid intermediate (Fig. 4.9). However, another pathway affording the *N*-arylhydroxamic acid intermediate can occur

Figure 4.9 Metabolic activation of benzidine in part via N-acetylation, leading to a reactive nitrenium ion that covalently binds to DNA nucleophiles.

by initial N-acetylation of benzidine followed by CYP-mediated N-hydroxylation of the amide nitrogen, which is similar to a mechanism for the N-hydroxylation of the heterocyclic aromatic amine 2-AAF [17]. The final bioactivation step occurs when NAT functions as an *N*, *O*-acyltransferase and catalyzes the intramolecular transfer of the acetyl group from the nitrogen to the oxygen to give an unstable *N*-acetoxyarylamine intermediate that decomposes to acetic acid and the chemically reactive nitrenium ion that covalently binds to DNA nucleophiles [17]. Alternative to the *N*-arylhydroxamic acid intermediate, in another pathway, an *N*-hydroxylated arylamine undergoes direct O-acetylation by NAT to give the unstable *N*-acetoxyarylamine derivative, as shown for the NAT-mediated bioactivation of *N*-hydroxy-2-AF that leads to an unstable *N*-acetoxy-2-AF intermediate [185]. Slow acetylators are prone to increase CYP1A2-mediated N-hydroxylation of bicyclic aromatic amine carcinogens, which then undergo bioactivation by O-acetylation catalyzed by NAT1 [2]. Heterocyclic aromatic amines are poor substrates for N-acetylation by NAT1 and NAT2 and therefore undergo hepatic CYP1A2-mediated N-hydroxylation followed by NAT-catalyzed O-acetylation to the unstable *N*-acetoxyarylamine intermediate. In general, fast acetylators can detoxify bicyclic aromatic amines to amide products in the liver, whereas fast acetylators may bioactivate heterocyclic *N*-hydroxylaromatic amines to unstable *N*-acetoxyarylamine derivatives that lead to the formation of DNA adducts and the initiation of carcinogenesis [2].

4.6 GLUTATHIONE CONJUGATION

Conjugation of reactive electrophiles with the endogenous tripeptide nucleophile GSH (γ -glutamyl-cysteinyl-glycine) is an important phase II biotransformation/detoxification pathway in drug metabolism. The distribution of GSH in tissues is variable, but generally is high (1–10 mM). In hepatocytes, there are two major pools of GSH: the cytosolic pool represents ~85% and the mitochondrial pool ~15%. The structural uniqueness of GSH is due to the arrangement of one of its two peptide linkages where the γ -carboxyl moiety of the glutamyl amino acid, rather than the α -carboxylic acid moiety, is bound to the cysteinyl-amine via a peptidase-stable amide bond. The cysteinyl-sulfhydryl group of GSH is a “soft” nucleophile that is able to react with soft electrophiles such as carbon in polarized double bonds (e.g., α,β -unsaturated ketones, quinones, and quinone imines) and alkyl halides. GSH also reacts with intermediate soft electrophiles such as the carbon of epoxides and nitrenium ions.

The conjugation of GSH with chemically reactive xenobiotics can also be catalyzed by GST enzymes (EC 2.5.1.18) [186]. GSTs are located in the cytosol and microsomal and mitochondrial fractions of the cell. GSTs function by catalyzing the formation of a highly reactive thiolate anion, via an active-site tyrosine or serine located in the GSH binding site that activates the sulfur, with subsequent nucleophilic attack with a hydrophobic electrophile present in the hydrophobic substrate binding site of the GST dimer [186]. The major forms of the GST enzymes are found in the cytosol and are homodimers that are grouped into four families, namely, alpha (A), mu (M), pi (P), and theta (T).

Conjugation of chemically reactive electrophilic xenobiotics or xenobiotic metabolites with GSH most often results in the formation of GSH adducts with increased chemical stability. For instance, well-known examples of chemically stable GSH adducts,

which account for, in most cases, the clearance of reactive, potentially toxic, substances from the body, include thioether-linked GSH adducts of acetaminophen, diclofenac, and naphthalene. However, as discussed below, some GSH adducts have also been shown to function as chemically reactive electrophiles in their own right and to be capable of leading to the covalent binding of xenobiotics to biological nucleophiles resulting in varied tissue toxicities [32,33].

Enzyme-mediated degradation of GSH adducts can also lead to reactive metabolite formation. This pathway occurs initially via an extracellular process specifically by γ -glutamyl transpeptidase (γ -GT) in the liver and the kidney as major tissue sites. For example, GSH adducts can be transported out of the hepatocyte into the plasma where they undergo interorgan transport into the kidney. Once in the kidney, GSH adducts are broken down first by γ -GT (EC 2.3.2.2), the only known enzyme to cleave GSH and GSH adducts appreciably, which functions by hydrolyzing the γ -glutamyl bond [187], leading to the formation of the corresponding cysteinyl-glycine-*S*-linked adducts (cys-gly adducts). Following the γ -GT step, cys-gly adducts undergo further hydrolysis by a cys-glydipeptidase (EC 3.4.13.6), or aminopeptidase N (also known as *aminopeptidase M*; EC 3.4.11.2), leading to the formation of the corresponding L-cysteine-*S* adducts [188]. L-Cysteine-*S* adducts then serve as substrates for cysteine-*S*-conjugate NAT (EC 2.3.1.80) [189], which functions to acetylate the cysteinyl-amine residue of these conjugates (via the cofactor acetyl CoA) affording *N*-acetylcysteine (NAC) adducts before excretion in urine. Cysteine-*S*-conjugates in addition to undergoing *N*-acetylation to mercapturates can also be metabolized by the renal cysteine conjugate β -lyase (EC 4.4.1.13), a pyridoxal-phosphate-dependent enzyme located in renal mitochondria and cytosol, leading to the cleavage of the cysteinyl C–S bond and the subsequent formation of sometimes unstable thiols that are proposed to function as nephrotoxic metabolites [190].

The examples discussed below include the bioactivation of xenobiotics resulting in the formation of chemically reactive GSH adducts (e.g., ethylene dibromide (EDB), α -naphthylisothiocyanate (ANIT), and carboxylic acid drugs) and chemically reactive mercapturic acid pathway degradation products of the corresponding GSH adducts (e.g., 3,4-methylene-dioxymethamphetamine, bromobenzene, sevoflurane, and hexachlorobutadiene).

4.6.1 Ethylene Dibromide Episulfonium Ion Formation

A well-known case of the formation of a GSH adduct mediating mutagenic and genotoxic effects is that of the industrial chemical EDB (Fig. 4.10) [18]. EDB is a haloalkane bifunctional electrophile that undergoes bioactivation by GST-catalyzed conjugation forming a reactive intermediate that leads ultimately to the formation of DNA adducts *in vivo* in rat and *in vitro* in rat and human hepatocytes [191–193]. The conjugation of EDB with GSH is known to be selectively catalyzed by both GST-A and GST-T classes of enzymes [193,194]. In this reaction mechanism, the thiol of GSH reacts with EDB in an S_N2 -type reaction leading to the elimination of bromide ion and the formation of a thioether-linked half sulfur mustard, which undergoes another round of bromide ion elimination via an intramolecular S_N2 reaction (β -elimination) with the sulfur atom to provide the chemically reactive episulfonium-ion-GSH adduct. The episulfonium-ion-containing GSH adduct is reactive with DNA, where the *N*⁷-guanine residue is a major target for DNA alkylation forming *S*-[2-(*N*⁷-guanylyl)ethyl]-GSH

Figure 4.10 Scheme for the bioactivation of ethylene dibromide via conjugation with GSH.

leading to damaged DNA and subsequent carcinogenicity (Fig. 4.10) [18]. The corresponding NAC adduct, namely, S -[2-(N^7 -guanyl)ethyl]-NAC, has been detected in the urine of EDB-dosed rats [195]. In summary, the GST-mediated conjugation of the haloalkane EDB with GSH leads to covalent binding to intracellular nucleophiles such as nucleic acids leading to mutagenic and carcinogenic effects.

4.6.2 3,4-Methylenedioxymethamphetamine-Induced Neurotoxicity: Mercapturic-Acid-Pathway-Dependent Bioactivation

3,4-Methylenedioxymethamphetamine (MDMA), also known as *Ecstasy*, is an illicit psychoactive drug that possesses stimulant and hallucinogenic properties [196]. However, MDMA also functions as a serotonergic neurotoxicant in many species, including nonhuman primates, which is thought to be mediated in part by neurotoxic metabolites of MDMA [23,197]. A proposed scheme for the metabolism of MDMA leading to neurotoxic metabolites is shown in Fig. 4.11 [23,198]. Thus, MDMA first undergoes metabolism in the liver by cytochrome P450s to nonneurotoxic metabolites either by CYP2B6-mediated N-demethylation forming methylenedioxyamphetamine (MDA) or by CYP2D6-mediated O-demethylation forming N -methyl- α -methyldopamine (N -methyl- α -MeDA). CYP-mediated O-demethylation of MDA leads to the formation of α -MeDA. Then, both of these o -catechol metabolites undergo further oxidation yielding chemically reactive o -quinone intermediates that are reactive with GSH forming 2- or 5-(glutathion- S -yl)- N -methyl- α -MeDA and 2- or 5-(glutathion- S -yl)- α -MeDA, respectively. Subsequent oxidation of these o -catechol-GSH adducts to reactive o -quinone intermediates, followed again by reaction with GSH, leads to the formation of the corresponding 2,5-bis-glutathionyl conjugates [23]. The hepatic formation of these

Figure 4.11 Proposed scheme for the metabolic activation of MDMA via P450, GSH conjugation, and mercapturic acid formation, leading to neurotoxic metabolites.

mono- and bis-GSH-linked adducts is followed by their interorgan transport and distribution into the brain by crossing the blood–brain barrier [199,200]. The GSH adducts can then undergo further metabolism by the mercapturic acid pathway in brain tissue or capillary lumen to the corresponding NAC derivatives, which are slowly eliminated from the brain leading to accumulation. The catechol-containing NAC adducts are proposed to undergo further oxidation in brain tissue leading to reactive oxygen species and chemically reactive *o*-quinone intermediates that arylate proteins leading to the development of MDMA-mediated serotonergic neurotoxicity. In summary, results from studies on the neurotoxic effects of MDMA showed that neurotoxic thioether-linked metabolites of MDMA derived from reactions of chemically reactive

o-quinone metabolites with GSH mediate the toxicity rather than the detoxification of the illicit drug.

4.6.3 Bromobenzene

Bromobenzene was formerly used as an industrial solvent; however, it is hepatotoxic and induces centrilobular necrosis by a mechanism consistent with P450-mediated bioactivation to chemically reactive benzoquinone-type metabolites [22,201]. In terms of bioactivation via GSH conjugation, bromobenzene also causes nephrotoxicity, where a crucial role for benzoquinone-derived GSH adducts has been elegantly established [24,202,203]. Thus, treatment of rats with radiolabeled [^{14}C]bromobenzene was shown to result in the development of renal necrosis and covalent binding of the radioactive molecule primarily to necrotic tubular cells, which provided evidence that the covalent binding to protein and necrosis are correlated [204]. The mechanism of bromobenzene-induced nephrotoxicity was proposed to occur whereby a reactive cytochrome P450-generated bromoquinone metabolite generated in the liver reacts covalently with hepatic GSH forming bromohydroquinone-linked thioether GSH adducts that undergo interorgan transport to the kidney where the GSH adducts are processed by the mercapturic acid pathway γ -GT and alanylaminopeptidase enzymes leading to bromohydroquinone-linked cysteine-*S*-conjugates (Fig. 4.12). These bromohydroquinone-linked cysteine-*S*-conjugates are known to readily undergo redox cycling leading to oxidative stress and the formation of bromoquinone-linked cysteine-*S*-conjugates that react covalently with protein. Renal cysteine conjugate β -lyase metabolism of the cysteine-*S*-conjugate was shown not to contribute to the nephrotoxicity of 2-bromo-(cystein-*S*-yl)hydroquinone in rats, where inhibition of the β -lyase did not diminish nephrotoxicity [24]. However, by contrast, in another study, inhibition of γ -GT led to diminished covalent binding to renal tissues and nephrotoxicity post administration of 2-[^{14}C]bromohydroquinone to rats [205]. In summary, the kidney necrosis observed in rats post administration of bromobenzene is strongly viewed to be due in part to 2-bromohydroquinone *S*-linked GSH adducts formed in the liver and then transported to the kidney, followed by conversion to ultimate nephrotoxic metabolite(s) by further mercapturic-acid-pathway-mediated degradation to the corresponding redox cycling sensitive cysteine-*S*-conjugates. One of the GSH adducts of bromobenzene, namely, 2-Br-3-(glutathion-*S*-yl)hydroquinone, was studied in detail *in vitro* in incubations with γ -GT. It was determined that the γ -GT-mediated cleavage of the γ -glutamate moiety leads to the freeing up of the nucleophilic cysteinyl-amine functional group in the 2-Br-3-(cystein-*S*-yl-glycine)hydroquinone product. Subsequent oxidation of the hydroquinone to the quinone derivative, which occurs readily, allows for the condensation of the α -amino-cysteine group with the carbonyl carbon of the quinone, leading to the elimination of water and the formation of the 1,4-benzothiazine product, 2*H*-(3-glyciny)-7-hydroxy-8-Br-1,4-benzothiazine. Elimination of glycine followed by coupling of two product benzothiazine derivatives leads to the formation of 2,3-bis-(1,4-benzothiazine) dimers, which can tautomerize and undergo subsequent coupling to form insoluble polymers [206]. It has been proposed that the deposition of insoluble polymers within the renal proximal tubules might contribute to the nephrotoxicity of the 2-Br-3-(glutathion-*S*-yl)hydroquinone conjugate [206].

Figure 4.12 Bioactivation via GSH conjugation, leading to benzoquinone-derived GSH adducts that mediate bromobenzene-induced nephrotoxicity.

4.6.4 Sevoflurane-Induced Nephrotoxicity: Renal Cysteine Conjugate β -Lyase-Dependent Bioactivation

The renal cysteine conjugate β -lyase pathway is an important mechanism for the metabolic activation of structurally varied nephrotoxic haloalkenes [19,190,207]. The initial step in this multistep bioactivation mechanism is the GST-catalyzed formation of GSH-*S*-conjugates in liver. After interorgan transport to the kidney, the GSH adducts undergo γ -GT- and dipeptidase-catalyzed hydrolysis in the proximal tubules to the corresponding cysteine-*S*-conjugates. Cysteine-*S*-conjugates that do not undergo detoxification by cysteine *N*-acetylation and conversion to mercapturates can be bioactivated by renal cysteine conjugate β -lyase to thioacylating intermediates that react with cellular nucleophiles leading to renal tissue necrosis. An example of renal cysteine conjugate

Figure 4.13 Glutathione conjugation- and cysteine β -lyase-dependent bioactivation of sevoflurane, leading to reactive metabolite formation, covalent binding to renal proteins, and nephrotoxicity.

β -lyase-dependent bioactivation is for the drug sevoflurane fluoromethyl 2,2,2-trifluoro-1-(trifluoromethyl)ethyl ether (Fig. 4.13). Sevoflurane is a volatile general anesthetic that was first used clinically in Japan in 1990 by Maruishi Pharmaceuticals and subsequently marketed in the United States and worldwide (1995) by Abbott Laboratories as Ultane[®] and Sevorane[®], respectively [208,209].

Sevoflurane has been shown to undergo chemical degradation when in contact with strong bases such as soda lime found in anesthesia circuits linked to carbon dioxide

scrubbers. This leads to the formation of 2-(fluoromethoxy)-1,1,3,3,3-pentafluoro-1-propene (compound A), a halogenated alkene that is nephrotoxic in rats and mediates the formation of proximal tubular lesions leading to tubular necrosis of the outer stripe of the outer medullary layer of the kidney [20,210]. Compound A is bioactivated by GSH-dependent metabolism, and two compound-A-derived GSH adducts, namely, *S*-[2-(fluoromethoxy)-1,1,3,3,3-pentafluoropropyl]-GSH (G1) and *S*-[2-(fluoromethoxy)-1,3,3,3-tetrafluoro-1-propenyl]-GSH (G2) and the two corresponding mercapturates, *S*-[2-(fluoromethoxy)-1,1,3,3,3-pentafluoropropyl]-NAC and *S*-[2-(fluoromethoxy)-1,3,3,3-tetrafluoro-1-propenyl]-NAC, are eliminated in the bile and urine, respectively, of rats administered compound A (Fig. 4.13) [211]. The GSH adducts G1 and G2, and the corresponding cysteine-*S* adducts, have been shown to be nephrotoxic in rats [212]. Results demonstrating that the inhibition of renal cysteine conjugate β -lyase partially protected against compound A renal toxicity provided evidence that this enzyme pathway may be important in the bioactivation of compound-A-derived GSH adducts leading to nephrotoxicity in rats. Compound A GSH adducts G1 and G2 undergo mercapturic acid pathway hydrolytic degradation by γ -GT followed by dipeptidase-mediated cleavage of glycine affording the corresponding compound A cysteine-*S*-linked adducts. The cysteine-*S*-conjugates are the penultimate metabolites in this bioactivation pathway and function as substrates for bioactivation by renal cysteine conjugate β -lyase, which forms the ultimate toxic reactive thionoacyl halide and thioketene species that react with renal cellular nucleophiles. However, no immunochemical evidence for renal protein adducts was found in male Wistar rats 24 h after the administration of the mercapturates or GSH adducts of compound A, which lead to renal corticomedullary necrosis. Such results were proposed to provide evidence against the involvement of cysteine conjugate β -lyase in compound-A-induced nephrotoxicity in rats [213].

In summary, the phase II mechanism of metabolism of compound A by GSH conjugation leading to cysteine-*S*-conjugate formation is proposed to mediate nephrotoxicity in rats via subsequent renal uptake and β -lyase-dependent bioactivation with the subsequent acylation of tissue proteins. Human (and rat) kidneys are injured by compound A produced by degradation of the clinically dosed (inhalation) sevoflurane. Renal injury in volunteers dosed with sevoflurane was shown to increase with increasing duration of exposure to a given concentration of compound A [214]; however, other investigations have shown no significant changes in either standard or experimental renal markers [213]. In comparison to rats, other than the report by Eger *et al.* [214], there has been no evidence for compound-A-induced nephrotoxicity in humans [215]. The differences in toxic potential have been proposed to be due to differences between species with regard to compound A exposure, renal cysteine conjugate β -lyase activity, and the relative reactive metabolite formation versus detoxification (i.e., mercapturate formation).

4.6.5 Hexachlorobutadiene-Induced Nephrotoxicity

Like sevoflurane, haloalkenes are also bioactivated after multiple enzyme steps involving GSH, the mercapturic acid pathway, and renal cysteine conjugate β -lyase leading to reactive electrophilic thioketene intermediates that covalently bind to renal tissue protein and lead to nephrotoxicity.

Hexachlorobutadiene, a polychlorinated alkene, is not a potent hepatotoxin, but a well-known nephrotoxicant in rodents that induces necrosis in the S-3 portion

Figure 4.14 Glutathione conjugation- and cysteine β -lyase-dependent bioactivation of hexachlorobutadiene, leading to reactive metabolite formation, covalent binding to renal proteins, and nephrotoxicity.

of the renal proximal tubule [216]. The metabolism of hexachlorobutadiene to a GSH adduct occurs in the liver where GST catalyzes the conjugation with GSH eliminating one chlorine atom and forming (*S*-pentachlorobutadienyl)-GSH. Then, (*S*-Pentachlorobutadienyl)-GSH, which is not chemically reactive, either is eliminated in bile or undergoes interorgan transport to the kidney where it is metabolized further by the mercapturic acid pathway enzymes by sequential cleavage of glutamic acid and glycine residues leading to the cysteine-*S*-conjugate, namely, (*S*-pentachlorobutadienyl)-L-cysteine [21]. (*S*-Pentachlorobutadienyl)-L-cysteine can undergo detoxification by N-acetylation via NAT leading to mercapturic acid or undergo bioactivation by renal cysteine conjugate β -lyase leading to the formation of a chemically reactive thioketene species, which covalently binds to cellular macromolecules leading to nephrotoxicity (Fig. 4.14).

4.6.6 α -Naphthylisothiocyanate-Induced Intrahepatic Cholestasis

An example of hepatic cholestasis that is proposed to be mediated by phase II GSH adduct formation of a corresponding reactive chemical comes from studies with the model compound ANIT. ANIT is a chemical which induces intrahepatic cholestasis, hepatocellular and biliary epithelial cell necrosis, bile duct obstruction, and biliary epithelial cell hyperplasia in rats [217] and is often used as a model reagent for human intrahepatic cholestasis. The isothiocyanate moiety of ANIT is chemically reactive and reacts readily with GSH in the liver forming an unstable thiocarbamoyl-GSH adduct

Figure 4.15 Proposed schemes for the mechanism of cholestasis and tissue damage mediated by (a) ANIT and (b) MIC, respectively, via conjugation with GSH.

(GS-ANIT) within the hepatocytes (Fig. 4.15a) [26]. ANIT is cytotoxic and induces morphological and functional changes in hepatocytes and leads to GSH depletion and the release of cytoplasmic enzymes [218]. The proposal for the mechanism of toxicity to biliary epithelial cells occurs whereby GS-ANIT is transported into bile by Mrp2, where the conjugate then dissociates back to ANIT and GSH [219]. The free ANIT becomes concentrated in the bile where it damages bile duct epithelial cells and induces cholangitis, followed by intrahepatic cholestasis [219]. Evidence toward this hypothesis of ANIT-induced cholestasis in rats comes from studies showing that Mrp2-deficient TR(-) rats were protected from ANIT-induced cholestasis. In addition, results from studies with hepatic GSH-depleted rats (via treatment with buthionine sulfoximine) showed protection against hepatotoxic doses of ANIT [220]. In summary, phase II conjugation of ANIT with GSH leads to the formation of reversible GS-ANIT conjugate that allows for the exposure of high concentrations of ANIT to the biliary epithelium and subsequent intrahepatic cholestasis.

Methyl isocyanate (MIC) is another chemically reactive, highly toxic chemical that causes multiorgan system toxicity (respiratory, cardiovascular, gastrointestinal, musculoskeletal, and immunological) in part via reaction with GSH, leading to the formation of an unstable GSH adduct [27,221]. MIC is a volatile liquid that is reactive with the cysteinyl thiol of GSH, and on inhalation of the vapor reacts with GSH in the lung forming the carbamate thioester product, namely, S-(N-methylcarbamoyl)-glutathione (SMG; Fig. 4.15b) [222]. Intraperitoneal administration of MIC to rats results in the excretion of SMG in bile and the corresponding mercapturate in urine [27,221]. The SMG conjugate is less reactive than MIC; however, it is known to be able to function as a carbamoylating agent under physiological conditions and to be cytotoxic to hepatocytes during incubation [223]. SMG formed in the lung is proposed to cross the alveolar-blood barrier and enter the systemic circulation where it undergoes interorgan transport to other tissues and mediates extrapulmonary toxicities after dissociating into MIC and GSH [221]. Thus, similar to ANIT and its thiocarbamoyl-GSH adduct, the GSH adduct of MIC formed *in vivo* may serve as an interorgan transport vehicle for MIC to target organs of toxicity separate from the site of GSH adduct origin in the lung [27].

4.6.7 S-Acyl-Glutathione Thioester Adducts of Carboxylic-Acid-Containing Drugs

As discussed in the section on acyl-CoA-thioester-mediated bioactivation, carboxylic-acid-containing drugs can be metabolically activated to chemically reactive *S*-acyl-CoA thioesters (as well as intermediate acyl-adenylates) that are able to transacylate the cysteinyl thiol of GSH, forming drug-*S*-acylated-GSH (*S*-acyl-GSH) adducts [34]. *S*-Acyl-GSH adducts are increasingly being shown as metabolites of carboxylic-acid-containing compounds *in vivo* and *in vitro*. They have been detected in the bile of dosed rats and from studies with rat and human hepatocytes incubated with bile acids [223], arylacetic acids [224,225], 2-arylpropionic acids [28], and fibric acids [226].

S-Acyl-GSH thioester derivatives are chemically reactive and have been shown to readily transacylate NAC *in vitro* [25]. Thus, it was demonstrated that when a range of 11 GSH thioesters of structurally varied carboxylic acid drugs were incubated with NAC in potassium phosphate buffer (pH 7.5, room temperature), the formation of the corresponding *S*-acyl-NAC conjugates occurred at a relative rate that depended on the extent of substitution at the α -carbon position next to the carbonyl carbon of the thioester linkage. The rank order of transacylation reactivity with NAC forming the corresponding *S*-acyl-NAC-thioesters was shown to be phenoxyacetyl- > arylacetyl- > 2-phenylpropionyl- $\approx$ α,α -dimethyl-phenoxyacetyl- > α,α -dimethyl-substituted-*S*-acyl-GSH. In these studies, the phenoxyacetyl-*S*-acyl-GSH derivatives tested were $\sim$ 3- and 26-fold more reactive with NAC than the arylacetic-acid- and profen-*S*-acyl-GSH derivatives examined, respectively, and no significant *S*-acyl-NAC thioester formation was observed with the α,α -dimethyl-substituted *S*-acyl-GSH derivative (gemfibrozil-*S*-acyl-GSH). Such results indicate that drug-*S*-acyl-GSH derivatives might be able to transacylate protein nucleophiles *in vivo*, such as on exposure to hepatobiliary proteins after excretion and concentration in bile, and thereby contribute to covalent binding of acidic drugs to tissue proteins; however, no experiments have been performed to date to test this proposal [100].

S-Acyl-GSH thioester derivatives can be degraded by γ -GT via cleavage of the γ -glutamyl group leading to *S*-acyl-cysteinyl-glycine (*S*-acyl-cys-gly) thioester-linked products that spontaneously rearrange to the corresponding *N*-acyl-cys-gly amide-linked conjugates (Fig. 4.16) [227–229]. Further dipeptidase-mediated cleavage of glycine leads to *N*-acyl-cys amide products. These cys-gly and cys amide products have been detected in the bile and urine of dosed animals. From the examples provided above, drug-*S*-acyl-linked-NAC adducts would not be expected to be the adducts of interest examined for in urine as markers of drug-*S*-acyl-GSH adduct formation occurring *in vivo*. Drug-*N*-acyl-cys or *N*-acyl-cys-gly derivatives should be employed as markers of *S*-acyl-GSH adduct formation occurring *in vivo* when studying bile and/or urine extracts obtained from preclinical species or patients dosed with carboxylic-acid-containing drugs that may become metabolically activated by *S*-acyl-CoA formation since the corresponding mercapturate derivatives, except for one literature report [230], most often are not detected *in vivo*.

In addition to the potential transacylation of protein nucleophiles by *S*-acyl-GSH thioesters, the formation of drug-*N*-acyl-cys or *N*-acyl-cys-gly free-sulphydryls and subsequent exposure to the extracellular canalicular membrane of the bile duct epithelium and/or the external surface of the proximal renal tubules of the kidney, as well as the increased concentration of γ -GT and dipeptidase enzyme activity in those tissue

Figure 4.16 Proposed scheme for the γ -GT- and dipeptidase-mediated degradation of *S*-acyl-GSH thioesters, leading to the formation of *N*-acyl-cys-gly and *N*-acyl-cys amides, respectively.

sites [231], could potentially lead to these sulfhydryl derivatives covalently binding via disulfide bond formation to protein-cysteinyl-sulfhydryls. Examples of drugs containing a free-sulfhydryl moiety that are believed to be responsible for allergic rash due to drug–protein disulfide-linked adducts mediating immune reactions are the angiotensin-converting enzyme inhibitor captopril and the immunosuppressive agent D-penicillamine. Potentially, *N*-acyl-cys and *N*-acyl-cys-gly metabolites of acidic drugs formed from precursor *S*-acyl-GSH adducts could be contributors to covalent binding to protein *in vivo* and subsequent idiosyncratic drug reactions of some carboxylic-acid-containing drugs linked to liver and kidney toxicities, for instance, BNX [88] and diclofenac [10].

In summary, as demonstrated by the examples discussed above, the phase-II-mediated transfer of GSH to a xenobiotic does not always function to detoxification but, by contrast, sometimes leads to the formation of toxic GSH adducts that mediate oxidative stress and/or covalent binding to macromolecules, including DNA and protein.

4.7 ACYL-S-CoA FORMATION

A requirement for phase-II-mediated conjugation reactions of carboxylic-acid-containing compounds, for example, amino acid conjugation with glycine or glutamine, taurine amide formation, and carnitine ester formation, is that they must first be activated to *S*-acyl-coenzyme A (*S*-acyl-CoA) thioester-linked intermediates [232–235]. Therefore, acidic drugs are often substrates for biotransformation by *S*-acyl-CoA formation leading to the generation of chemically reactive electrophiles that serve as necessary substrates for conjugating enzymes such as acyl CoA:amino acid *N*-acyltransferase (Fig. 4.17) [34,58,62,236–238]. However, chemically reactive *S*-acyl-CoA thioesters have also been shown to mediate the transacylation of cellular protein nucleophiles and are therefore similar to reactive acyl glucuronides,

Figure 4.17 Acyl-CoA-synthetase-mediated formation of *S*-acyl-CoA thioesters via the reactive acyl-adenylate intermediate, leading to the transacylation of GSH and protein nucleophiles.

proposed to mediate idiosyncratic allergic toxicity for a range of acidic drugs [34,50,51,237,238].

S-Acyl-CoA thioester formation is catalyzed by acyl CoA synthetases (EC 6.2.1.1–EC 6.2.1.3) located in the endoplasmic reticulum, the outer membrane of mitochondria (long-chain fatty acid acyl CoA synthetases), and the mitochondrial matrix (short-, medium-, and branched-chain acyl CoA synthetases). The acyl-CoA-synthetase-mediated catalysis of *S*-acyl-CoA thioester formation requires the cofactors ATP and coenzyme A (CoASH) and proceeds via a two-step reaction mechanism involving the formation of a chemically reactive acyl-adenylate intermediate (acyl-AMP; Fig. 4.17) [239]. Unlike short-, medium-, and long-chain endogenous fatty acid *S*-acyl-CoA thioesters, which are efficiently metabolized by fatty acid β -oxidation, xenobiotic *S*-acyl-CoA thioester derivatives, such as those formed from the metabolism of profen- and arylacetic-acid-containing drugs, are not degraded by fatty acid β -oxidation. Therefore, if xenobiotic *S*-acyl-CoA thioesters are not eliminated by conjugation with glycine or taurine, these reactive derivatives might accumulate in the cell and lead to the transacylation of protein nucleophiles resulting in the formation of drug–protein adducts [240]. The potential of chemically reactive xenobiotic *S*-acyl-CoA thioesters to mediate the toxicity of certain carboxylic-acid-containing drugs is not known; however, increasing investigations on the chemical and biochemical properties of these intermediates performed over the last two decades have provided necessary insight into their potential importance

with regard to mediating covalent binding to protein, and hence potential toxicity [34,58,233,239,241].

4.7.1 *S*-Acyl-CoA Thioesters

The inherent chemical reactivity of *S*-acyl-CoA intermediary metabolites of carboxylic acid-containing drugs is due to the presence of an electrophilic carbonyl carbon at the *S*-acyl linkage [242]. Because of their large size and amphipathic properties, xenobiotic acyl CoA thioesters do not leave the intracellular space but serve as substrates for phase II metabolism by conjugation with amino acids, carnitine, and sometimes glycerol esters, yielding hybrid triglycerides [243]. Again, these transacylation-type conjugation reactions are enzyme mediated and require a chemically reactive thioester carbonyl carbon that leads to amide or ester product formation. A growing number of studies have shown that xenobiotic *S*-acyl-CoA thioesters are chemically reactive intermediates and are able to transacylate endogenous nucleophiles such as glycine; protein amino, hydroxyl, and sulfhydryl groups; and the cysteinyl sulfhydryl of GSH. For example, salicylic acid *S*-acyl-CoA thioester was shown to react nonenzymatically with glycine, leading to the formation salicyluric glycine amide [244]. Results from additional studies have demonstrated that long-chain acyl CoA derivatives including palmitoyl CoA, arachidonyl CoA, and retinoyl CoA react nonenzymatically with cysteinyl sulfhydryls of proteins and peptides [245–247]. Many recent examples of chemically reactive *S*-acyl-CoA thioesters from both endogenous and xenobiotic origins include those formed from the bile acid cholic acid [248]; the hypolipidemic drugs clofibric acid [25], bezafibrate [240], and nafenopin [240,249]; and the NSAIDs ibuprofen [28], flunoxaprofen [250], naproxen [251], tolmetin [234], and zomepirac [235]. The prediction of *S*-acyl-CoA thioesters for their ability to covalently bind to protein based on their chemical structures has been examined [252]. It was determined that similar to the chemical reactivity of acyl glucuronides (discussed above), the *in vitro* chemical reactivity of *S*-acyl-CoA thioester derivatives with biological nucleophiles, such as GSH, decreases with increasing substitution at the carbon adjacent to the carbonyl carbon of the carboxylic acid moiety [252]. Thus, the chemical reactivity of eight structurally varied synthetic *S*-acyl-CoA derivatives with GSH was tested *in vitro* [252]. The *S*-acyl-CoA thioesters studied were prepared from the carboxylic acids (*R*, *S*)-ibuprofen, clofibric acid, indomethacin, fenbufen, tolmetin, salicylic acid, (*R*, *S*)-2-phenoxypropionic acid, and 4-chloro-2-methylphenoxyacetic acid (MCPA). The chemical structures (Table 4.2) of these acids differ from one another by the substitution of methyl groups at the α -carbon, by having an oxygen atom in place of a methylene group at the β -position, and/or by the location of an *o*-hydroxy group on a benzoic acid moiety. Results from reactivity experiments showed that the relative reactivity of the *S*-acyl-CoA derivatives with GSH (0.1M potassium phosphate buffer, pH 7.4, 37°C) was dependent on (i) the increased extent of methyl group substitution at the α -carbon leading to decreased rates of reaction, (ii) the placement of an oxygen atom in place of the β -position methylene group leading to increased reactivity, and (iii) *o*-hydroxy group substitution of benzoic-acid-type acids, which leads to increased reaction rate forming the corresponding *S*-acyl-GSH derivatives. Therefore, the rank order of reactivity for the *S*-acyl-CoA thioester derivatives tested with GSH was phenoxyacetic acid > *o*-hydroxybenzoic acid

$\sim(R, S)$ -2-phenoxypropionic acid > arylacetic acid derivatives > 2-methyl- (R, S) -2-phenoxypropionic acid $\sim(R, S)$ -2-PPA. As a specific example, it was shown that the S -acyl-CoA thioester derivative of the phenoxyacetic acid MCPA was approximately fourfold more reactive than salicylic acid S -acyl-CoA and was 120-fold more reactive than ibuprofen- S -acyl-CoA in reactions with GSH, leading to S -acyl-GSH thioester adduct formation.

A strong relationship between S -acyl-CoA formation and covalent binding to protein *in vitro* and *in vivo* has been shown [238,249,253,254]. For example, mechanistic covalent binding studies in rat hepatocytes were performed in order to examine the correlation between metabolism of (R, S) -2-PPA to a reactive acyl glucuronide or acyl CoA thioester that leads to covalent binding to hepatocyte protein [238]. Results showed that the time course profile of covalent binding of radioactive molecule to protein correlated with 2-PPA- S -acyl-CoA formation and not with 2-PPA-1- β - O -G formation. In addition, *in vitro* studies in rat hepatocytes incubated with radioactive (R)- or (S)-2-PPA isomers showed enantioselective covalent binding to protein ($R/S = 4.5$) that correlated with enantioselective 2-PPA- S -acyl-CoA formation ($R/S = 7.0$), but not with 2-PPA-1- β - O -G formation ($R/S = 0.7$). Such results were consistent with data from inhibition studies where the covalent binding of 2-PPA to hepatocyte protein was found to decrease by 53% in cells treated with trimethylacetic acid that resulted in a 66% decrease in 2-PPA- S -acyl-CoA formation occurred. The complete inhibition of 2-PPA-1- β - O -G formation only led to a 19% decrease in covalent binding to protein. Corresponding studies performed *in vivo* in rats showed that covalent binding of 2-PPA to liver proteins was decreased by $\sim 50\%$ in rats pretreated with trimethylacetic acid (64% decrease in hepatic 2-PPA- S -CoA exposure), whereas pretreatment with (–)-borneol, which inhibited the exposure of 2-PPA acyl glucuronide by 95%, only decreased covalent binding to hepatic protein by 23% [238]. Such results clearly demonstrate that metabolism of 2-PPA by S -acyl-CoA formation contributed to the covalent binding to protein more than did bioactivation of 2-PPA by acyl glucuronidation.

In terms of the ability of S -acyl-CoA thioesters to transacylate GSH, the enantioselective formation of S -acyl-GSH thioesters has been investigated with the chiral profen drugs ibuprofen and flunoxaprofen [28,250]. Experiments with ibuprofen led to the detection of the ibuprofen- S -acyl-GSH thioester (ibuprofen- S -acyl-GSH) during incubation with rat hepatocytes. Results obtained from the tandem mass spectrometric analysis of extracts from incubations with enantiomerically pure (R)- and (S)-ibuprofen isomers showed that ibuprofen- S -acyl-GSH formation, in addition to having a time course of formation that was consistent with the time course profile of ibuprofen- S -acyl-CoA but not with ibuprofen-1- β - O -acyl glucuronide (ibuprofen-1- β - O -G) formation, was highly enantioselective for the (R)-antipode. In addition, data from enzyme inhibition experiments demonstrated that inhibition of ibuprofen- S -acyl-CoA formation (by coincubation with lauric acid), and not ibuprofen-1- β - O -G production (by coincubation with [–]-borneol), led to a corresponding decrease in ibuprofen- S -acyl-GSH formation. Therefore, chemically reactive ibuprofen- S -acyl-CoA thioester, and not the ibuprofen-1- β - O -G metabolite, led to the transacylation of hepatocyte GSH. Results from similar studies with (R)- and (S)-flunoxaprofen showed the highly stereoselective transacylation of GSH by (R)-flunoxaprofen forming flunoxaprofen- S -acyl-GSH during incubation with rat hepatocytes, which provided further evidence for the primary involvement of S -acyl-CoA thioester intermediates, rather than 1- β - O -acyl glucuronide

metabolites, in the bioactivation of carboxylic-acid-containing drugs leading to the transacylation of GSH [250].

4.7.2 Acyl-Adenylates (Acyl-AMP Intermediates)

The detection of intermediate mixed anhydride adenosine 5-monophosphate (AMP) adenylate derivatives of xenobiotic and endogenous carboxylic acids during the biosynthesis of their corresponding *S*-acyl-CoA thioesters has been demonstrated [255–257]. Acyl-AMP intermediates, such as those detected from the metabolism of the bile acid cholic acid, are chemically reactive because they have an electrophilic carbonyl carbon in the mixed anhydride linkage that can react nonenzymatically with nucleophiles. Recently, bile acid acyl-AMP intermediates were shown to be reactive in transacylation-type reactions with peptides and proteins and with the thiol group of GSH, leading to the formation of bile acid *S*-acyl-GSH conjugates [29,257,258]. From incubations of cholic acid with rat liver microsomes fortified with cofactors for acyl CoA formation (ATP, CoASH, and Mg^{2+}), cholyl-acyl-AMP was detected in concentrations similar to the cholyl-*S*-acyl-CoA thioester [256]. Further studies showed that the reactivity of cholyl-acyl-AMP and cholyl-*S*-acyl-CoA with GSH in buffer under physiological conditions (pH 7.4, 37°C) resulted in almost identical rates of cholyl-*S*-acyl-GSH formation. Therefore, both the *S*-acyl-CoA thioester and the acyl-AMP intermediate would be predicted to be important with respect to the transacylation of protein nucleophiles, leading to covalent binding to protein. In addition to endogenous bile acids, xenobiotic carboxylic acids, for example, of the anticonvulsant drug valproic acid and the NSAID ibuprofen are also metabolized to detectable acyl-AMP intermediates. The acyl-adenylate intermediate of valproic acid was shown to be formed in incubations with rat liver mitochondria (fortified with ATP and CoASH) and rat hepatocytes where it exists in part in the nonbound form to the acyl CoA synthetase enzyme [259]. Similar observations were made with (*R*)-ibuprofen, during incubations with rat liver mitochondria (also fortified with ATP CoASH) [255], where the corresponding acyl-adenylate intermediate was detected. For both valproyl-AMP and ibuprofenyl-AMP, their chemical reactivity with GSH or protein nucleophiles was not investigated.

In summary, carboxylic-acid-containing compounds can be bioactivated by acyl CoA synthetases leading to the generation of chemically reactive acyl-AMP and *S*-acyl-CoA intermediates that are able to mediate the transacylation of protein nucleophiles and therefore may be responsible, in addition to reactive acyl glucuronides, for contributing to covalent binding to protein that potentially leads to the initiation of untoward hypersensitivity reactions [34,58].

4.8 CONCLUSIONS

It is clear from the examples provided above that the metabolism of xenobiotics to chemically reactive intermediates is a major concern due to the potential of reactive metabolites to covalently bind to DNA or protein in the body leading to carcinogenesis, acute tissue damage, and/or immune-based idiosyncratic toxicities. In most cases, phase-II-mediated biotransformation of xenobiotics and/or xenobiotic metabolites leads to their deactivation, clearance, and detoxification by converting them to increasingly

hydrophilic substances that are efficiently excreted from the body. By contrast, this chapter has dealt with many cases of known mechanisms involved in the bioactivation of xenobiotics by phase II enzymes to chemically reactive metabolites and the toxicological significance that results from their covalent binding to cellular macromolecules including nucleic acids and proteins. Glucuronidation of carboxylic-acid-containing drugs and arylhydroxamic-acid-containing compounds can generate electrophilic acyl glucuronides and N–O-linked glucuronides, leading to allergic toxicity and carcinogenicity, respectively. There have been increasing examples of chemically reactive acyl glucuronide metabolites that have led to a greater appreciation and understanding of the potential role of glucuronidation in the carboxylic acid drug immune-mediated toxicity. O-Sulfonation of allylic and benzylic alcohol-, and arylhydroxylamine-containing compounds catalyzed by SULTs leads to highly electrophilic carbocations and nitrenium ions, respectively, that react with cellular DNA and protein and are mutagenic and carcinogenic in preclinical species and humans. N-Acetylation of hydrazines and aromatic amines, together with cytochrome P450-mediated bioactivation, leads to the formation of reactive acylating radicals and acetoxylaromatic amines, respectively, which react covalently with cellular macromolecules that mediate liver damage and carcinogenicity. Conjugation of reactive metabolites with GSH in the liver sometimes leads to GSH adducts that undergo further bioactivation after transport to the kidney by enzymes of the mercapturic acid pathway to chemically reactive, nephrotoxic metabolites. Therefore, some phase II metabolites, for instance, acyl glucuronides and GSH adducts, may distribute to organs different from the site of formation in the liver, leading to covalent binding to protein and subsequent extrahepatic toxicity. To date, there is strong evidence that the metabolism of carboxylic-acid-containing compounds by acyl CoA formation leads to the generation of reactive *S*-acyl-CoA and/or acyl-adenylate intermediates that can transacylate tissue proteins and are therefore potentially linked to immune-mediated toxicity. However, definitive evidence that these reactive intermediates mediate toxicity is not yet available, even though data on arylacetic-acid-containing NSAIDs demonstrates a causative association with reactive *S*-acyl-CoA, and/or acyl glucuronide, formation and hypersensitivity reactions in patients. The role of phase I oxidative enzymes such as cytochrome P450s often has an important part in the formation of protoxicants that has a determining effect on glucuronidation-, O-sulfonation-, N-acetylation-, and GSH-dependent bioactivation. Therefore, knowledge of the balanced coordination between phase I and phase II metabolism is important for understanding the role of reactive metabolites and subsequent toxicity in varied tissues. Just as in the case of phase I enzymes, polymorphic differences in phase II enzyme gene expression in humans are proposed to lead to differential susceptibility to potentially toxic xenobiotics. In summary, an increased understanding of the factors that influence the disposition of phase II metabolites of xenobiotics will be fundamental in understanding their potential biological, pharmacological, and toxicological effects.

ACKNOWLEDGMENTS

M. P. G. would like to thank Dr. Christian Skonberg (Department of Pharmaceutics and Analytical Chemistry, University of Copenhagen, Denmark), Howard Horng (Department of Biopharmaceutical Sciences, School of Pharmacy, University of California, San Francisco), and Dr. Yohannes Teffera and Dan Waldon (Department

of Pharmacokinetics and Drug Metabolism, Amgen Inc.) for their helpful discussions and suggestions during the writing of this chapter.

5.1 INTRODUCTION

Drug-induced liver injury (DILI) represents by far the most common cause for added label warnings or drug withdrawal and accounts for ~13% of cases of acute liver failure in the United States [1–4]. Implicit in this statistic is that preclinical safety studies currently performed as part of compiling a drug registration dossier offer limited predictive value for hepatotoxicity potential in humans. Other human toxicities with poor correlations with animal studies include hypersensitivity and cutaneous reactions [5]. The form of DILI of most concern is idiosyncratic hepatocellular injury that occurs in a small percentage of patients (1/10,000–100,000) and hence is detected only in large patient populations typically after the drug has received marketing approval. Significantly, the majority of such cases (60–80%) will, without liver transplantation, result in death [6–8]. Of the drugs that have FDA black box hepatotoxicity warnings, many are known to undergo bioactivation and produce reactive metabolites capable of covalently binding to endogenous proteins (Table 5.1) leading to a hypothesis that a link exists between drug bioactivation, the formation of drug–protein adducts, and downstream toxicity [9,10]. Adding merit to this hypothesis is the finding that drugs that are poorly metabolized rarely cause idiosyncratic liver toxicity or hypersensitivity reactions. Moreover, since tissue damage (e.g., liver, kidney, blood, and skin) is typically regiospecific to the site of metabolic activation, the link between these two

events is compelling [11]. The finding, however, that drug–protein adduct formation does not always equate with toxicity provides a level of complexity which continues to provide a challenge to the pharmaceutical industry. The question essentially becomes one of how to translate such information derived in early stage drug discovery and development into a risk assessment of relevance to patients?

Idiosyncratic drug reactions generally occur within the therapeutic range, are not associated with the pharmacology of the compound, are dose dependent in susceptible patients, but often occur at disparate dose levels in different patients receiving the same drug. There is also an induction period for onset of symptoms after first exposure to the drug (greater than two weeks) but with an acute response upon drug rechallenge (<24 h) with typical immune system manifestations such as fever and eosinophilia. The unpredictable nature of these adverse events essentially results in the removal of a medication that would otherwise benefit the majority of patients. Hence, there is a desire to understand the etiology of these idiosyncratic reactions with a view to developing screening tools, which could either halt the further development of such drugs in preference for others that have an improved safety profile or tools that could prospectively identify patients who are safe to receive such medications. In the absence of these tools, the fall-back position is to design drugs with minimal potential to form reactive metabolites at least as one strategy aimed at minimizing the potential for downstream toxicities, and hence avoid the associated patient safety issues and economic consequences of drug withdrawal.

Adverse drug reactions are often referred to as either *predictable* or *unpredictable* [12,13]. Predictable adverse reactions are dependent on the on- or off-target pharmacological properties of the drug and increase in intensity with increased dose and are ameliorated when the dose level is reduced. Examples of pharmacological on-target adverse reactions include the development of hypotension (antihypertensives) or hemorrhaging (anticoagulants), essentially indicative of a suprapharmacological response. An example of a pharmacological off-target reaction is ventricular arrhythmia associated with the HERG binders, astemizole, cisapride, and grepafloxacin [14,15].

Importantly, these predictable pharmacologically based reactions are mediated by parent compound or metabolites, which are *stable* and circulate in the systemic circulation; hence metabolite quantification has recently become a more highly regulated part of the drug development process [16] and has been formalized in an International Conference on Harmonization (ICH) M3(R2) guidance (<http://www.ich.org/cache/html/501-272-1.html>). Unpredictable adverse drug reactions are considered to result from metabolic activation (“bioactivation”) of a drug (=prohaptén), which results in the formation of typically *unstable* reactive metabolites capable of binding to endogenous macromolecules; a process often referred to as *hapténization*. From an immunological viewpoint, adducted proteins are “nonself” or “modified self” products that may provoke immune responses against themselves [17]. In the case of an idiosyncratic hypersensitivity response (e.g., halothane [17,18] and tienilic acid [19]), T-cell sensitization requires that drug-modified biomolecules are taken up by antigen presenting cells and transported into the local draining lymphoid tissue, where they are processed and presented on major histocompatibility complexes (MHC). The derived antigen-experienced T-cell progeny have specific tissue-homing properties. Therefore, in the case of a hypersensitivity reaction, it is the cytotoxic mechanism elicited by T-cells and not the drug alone, which damage tissue cells [20]. This type of toxicity should be distinguished from direct, acute, reactive-metabolite-mediated toxicity, albeit they both initially involve drug bioactivation and formation of a drug–protein adduct. A good example of the latter is acetaminophen, which is very safe when taken as directed but becomes predictably toxic in overdose situations and hence does not satisfy the criteria of an idiosyncratic (highly individualized, unpredictable) immune-mediated toxicant. The mechanism of this toxicity is well understood, whereby following a high dose that depletes endogenous GSH, which would normally trap the substituted quinoneimine reactive intermediate, the quinoneimine reactive intermediate instead alkylates liver proteins some of which result in disrupting mitochondrial function leading to cell death and liver necrosis [21–23]. While not a primary focus of this review, mechanism-based inactivation (MBI) of CYP450 can represent a direct functional readout of bioactivation and can result in drug–drug interactions.

Controversy, therefore, still remains on how to view the formation of a covalent bond between drug-derived reactive intermediates and endogenous proteins since no single diagnostic test currently exists to ascertain the downstream toxicological consequences of such an event with any degree of certainty. Moreover, the mode of action of some therapeutics are actually predicated on a prior metabolic activation step [24,25] (Table 5.2), albeit for this class of compound there is awareness on behalf of medicinal chemists to focus preferentially on the drug design option of making such interactions covalent, but reversible, when possible [26]. The challenge for the pharmaceutical industry, therefore, is to develop strategies that continue to support basic science research in the area of DILI. This is especially important at a time when the currently available toolbox is largely limited to medicinal chemistry expertise to minimize the potential for drug bioactivation during lead optimization, and to the risk management strategies of the individual companies and approval bodies when assessing adverse event data arising during clinical development, pre- and post approval.

5.1.1 Idiosyncrasy of Drug Hypersensitive Reactions

The formation of a drug–endogenous protein adduct forms the basis of the haptén hypothesis of drug hypersensitivity [27]. These adducts both stimulate a T-cell

TABLE 5.2 Pharmaceuticals Covalently Interacting with Their Pharmacological Targets

Drug ^a	Reacting Functionality	Target
Amoxicillin (acylation)	B-lactam (I)	Serine-type D-Ala-D-alacarboxypeptidase
Orlistat (acylation)	Lactone (R)	Triacylglycerol lipase
Rivastigmine (acylation)	Carbamate (R)	Acetylcholinesterase
Clavulanate (acylation)	B-lactam (I)	B-lactamase
Aspirin (acylation)	Ester (R)	Prostaglandin endoperoxidase synthase
Warfarin (acylation)	Coumarin	Vitamin K epoxide reductase (warfarin sensitive)
<i>Isoniazid</i> (acylation)	Hydrazide (I)	Enol-acyl carrier protein reductase
<i>Disulfiram</i> (acylation)	Disulfide (I)	Aldehyde dehydrogenase
Fosfomycin (alkylation)	Epoxide	UDP- <i>N</i> -acetylgluc-osamine-1- carboxy-vinyl transferase
D-Cycloserine (alkylation)	Amine	Alanine racemase
Vigabatrin (alkylation)	Amine (I)	GABA-AT
<i>Exemstane</i> (metal/metabolite binding)	Methyl (I)	Aromatase
Bortezomib (metal/metabolite binding)	Boronic acid (R)	Proteasome
<i>Omeprazole</i> (disulfide bond formation)	Sulfonamide (I)	H ⁺ /K ⁺ ATPase
<i>Clopidogrel</i> (disulfide bond formation)	Thiol (I)	P2Y ₁₂ purinoreceptor antagonist
Propylthiouracil	Thiourea	Seleno-enzyme
VX-950 (hemiketal formation)	Ketoamide (R)	Serine protease hepatitis C virus NS3
<i>Gemcitabine</i> (Michael addition)	Vinyl ketone	Ribonucleosidediphosphatereductase
Floxuridine (Michael addition)	Unsaturated amide (R)	Thymidylate synthase
Finasteride (Michael addition)	Unsaturated amide (R)	5- α -reductase
<i>Selegiline</i> (Michael addition)	Aceylenic imine (I)	Monoamine oxidase-B
Vildagliptin (Pinner reaction)	Nitrile (R)	Dipeptidylpeptidase (DPP)-IV
Odanacetib (Pinner reaction) (MK-0822)	Nitrile (R)	Cathepsin K

^aProdrugs are italicized and the chemical mechanism of drug–protein interaction is placed in parenthesis: I, irreversible interaction and R, reversible interaction.

proliferation and provide an antigenic signal to direct the effector arm of the immune system to the tissue cells, ultimately leading to tissue damage and potential toxicity. Indeed, Castrejon *et al.* [28] recently reported on the inhibitory effect of GSH on sulphamethazole nitroso metabolite-mediated T-cell proliferation, providing evidence for the role of drug–protein adduct formation in this process. Matzinger [29] laid down the fundamental premise of the importance of a “danger signal” in the context of an immune response and essentially stated that the primary goal of the immune system is to protect against danger; in the absence of danger tolerance prevails and in the presence of danger (e.g., underlying disease state, which might be asymptomatic, or a more obvious medical condition such as a viral infection) a full immune response ensues. Uetrecht [30–32] matured this concept by proposing the “danger hypothesis” that aimed to account for the very low incidence of idiosyncratic drug reactions encountered in patients. That is, contrary to what might be a natural outcome from the hapten hypothesis, not all drugs that form protein adducts mediate an immune response that results in toxicity. Uetrecht [32] proposed that this trigger could be provided by a “danger signal” and that the susceptibility of patients is increased through a culmination of genetic, environmental, and existing health factors that make some individuals more predisposed to aberrant outcomes resulting in a subtle though significant shift of the dose–toxicity response curve to the left. In support of this conclusion, antibodies to diclofenac adducts were detected in all diclofenac-induced liver injury serum samples, but they also occurred in 60% of individuals who had received the drug without DILI [33,34]. The candidate signal(s) that could sense danger could be exogenous (e.g., bacterial antigen) [35] or endogenous, to include heat shock protein (Hsp72) and high mobility group box 1 (HMGB1), since such molecules are produced when the body is under stress (e.g., viral infections or trauma coupled to drug-induced tissue necrosis) and are able to alert the immune system to mount an appropriate immune response [36,37] (see below). In summary, drug–protein adduct formation leads to cell damage, an insult that in turn produces a “danger signal” that can ultimately result in a B-cell-mediated antibody or cytotoxic T-cell-mediated response. Interestingly, Pirmohamed *et al.* [27] speculated that in certain instances, the nature of the insult provided by the reactive intermediate to the cell may be sufficiently large so as to overcome its ability to launch an immune response [27]; as might be the case for acetaminophen. This group speculated further that it may be possible to prime patients to have greater resilience against developing immune-mediated toxicities by starting at lower doses and increasing the dose slowly, which has been a successful strategy for both lamotrigine [38] and cotrimoxazole [39]. This proposal was based on the notion that at low doses, or low levels of reactive intermediate formation, only the initial part of the immune cascade is launched, that of an interaction between a MHC-restricted antigen and a T-cell receptor, resulting in tolerance, not a full blown immune response.

In addition to the danger hypothesis proposed by Uetrecht, which is drug metabolism dependent, Pichler, Tilch, and Schnyder [20,40] have reported that drugs can interact directly with T-cell receptors *without* previous metabolism or need to bind to proteins, and have coined this as “pharmacological interaction” (p-i) hypothesis [41,42]. This was based on the observation that clones of lymphocytes from patients with a history of an idiosyncratic drug reaction to sulfamethoxazole (in the lymphocyte transformation test (LTT) *in vitro*), proliferated in response to sulfamethoxazole in the absence of metabolism. According to this hypothesis, T-cells must express a T-cell receptor that can bind drug and induce a stimulatory signal with a low threshold for activation.

In addition, the T-cell receptor needs to interact with the MHC on antigen presenting cells in order to enhance the response to the drug. Lymphocytes from CBZ- (carbamazepine) treated patients also were observed to proliferate with therapeutic concentrations of CBZ (5–10 μM [43]) *in addition to* the CBZ-10,11-epoxide and 10-hydroxy-CBZ metabolites (but not other CBZ metabolites), which indicates that patients have T-cells that are specific for CBZ stable metabolites, a finding that is compatible with the p-i hypothesis. This hypothesis is also applicable to ximelagatran, a peptide like molecule [32], which is believed to form a low affinity association directly with MHC molecules as defined in a competition peptide–MHC binding assay [44]. These overall observations have led Wu *et al.* to speculate that a T-cell response, once activated, can become more generalized across a drug structure class. They cite administration of oxcarbazepine, a prodrug of 10-hydroxy-CBZ, to CBZ-hypersensitive patients as potentially leading to reactivation of preexisting memory T-cells and the development of a hypersensitivity reaction [45], and also the potential contraindication of structurally related antimicrobial sulfonamides in sulfonamide allergic patients [28].

5.1.2 Skin Reactions

The development of a skin reaction is probably the most obvious phenotype of a hypersensitive drug reaction, but how do drugs taken orally mediate such reactions? One proposal is that following distribution to the skin, skin cells are capable of metabolically activating drugs leading to allergic skin reactions [46], which is consistent with the hypothesis that tissue damage is regiospecific to the site of metabolic activation (see above). This has been postulated for the anti-HIV pharmaceutical, nevirapine (nevirapine $\rightarrow$ 12-hydroxylation $\rightarrow$ quinonemethide) [47,48], and the anticonvulsants lamotrigine (lamotrigine $\rightarrow$ 4'-5'- or 5'-6'-epoxidation $\rightarrow$ thioether conjugates) [49] and CBZ (CBZ $\rightarrow$ CBZ-10,11-epoxide and CBZ-2,3-epoxide [50,51]) (Fig. 5.1). In a second proposal, selective migration of T-cell populations, potentially arising from drug bioactivation in the liver, kidney, or blood, to the skin, is believed to be mediated via the skin-homing receptor and cutaneous lymphocyte antigen, which has been shown to be present on T-cell clones from patients hypersensitive to, for example, lamotrigine [52]. Clearly it is difficult to weigh the relative importance of these last two pathways for those compounds that are metabolized to reactive intermediates in both the skin and liver. Lastly, chemokine receptors (CCR) are also believed to play a role in cell-selective cutaneous migration. Toxic epidermal necrolysis (TEN) is a blistering reaction caused by the cutaneous infiltration of cytotoxic CD8^+ T cells [53], whereas a different population, CD4^+ T cells, appear to be associated with generalized

Figure 5.1 Structures of nevirapine, lamotrigine, and carbamazepine.

exanthematous pustulosis [42,54]. Wu *et al.* [55] have investigated the CCR-mediated trafficking of CD8⁺ and CD4⁺ T cells into epidermal and dermis cells where such cells were shown to persist in blood of CBZ-hypersensitive patients. While CCR8 was determined to be responsible for the steady-state trafficking of memory T cells into healthy skin [56,57], CCRs such as CCR4 and CCR10 were determined to mediate selective entry of T cells into inflamed skin [55]. It appears, therefore, that both direct (bioactivation in the skin) and indirect (bioactivation by internal organs) mechanisms are potentially at play in the mediation of skin reactions.

5.2 INTERVENTION STRATEGIES TO PREVENT DRUG-INDUCED LIVER INJURY

The foregoing text should lead the reader to conclude that the science describing the link between drug–protein adduct formation and downstream toxicity is rapidly developing. Researchers agree that the formation of drug protein adducts has the potential to represent a pivotal first step in a spiral toward endpoint toxicity and that forming reactive intermediates is, therefore, an undesirable occurrence and should be avoided when selecting drug candidates. Pragmatically, this could be rephrased to state that in the absence of a general understanding of the link between bioactivation and toxicity, the formation of reactive intermediates should be minimized as much as possible within reasonable discovery timeframes during the selection of drug candidates. In 2004, Merck & Co. translated these statements in to a strategy that could be adopted by the pharmaceutical industry [10]. Of note, Merck & Co. no longer routinely conducts covalent binding studies, but the relative merit and limitations of such studies are discussed since they are used by other companies (see below). Regardless, the core of this strategy, that of minimizing the potential for metabolic activation during the lead optimization stage of drug design, remains intact and has been broadly adopted in the pharmaceutical industry. The functional execution of the strategy, however, has been tailored by individual companies to meet their specific organizational needs, scientific expertise, and resource availability, some of which is now described.

5.2.1 Strategy to Minimize Potential for Reactive Intermediate Formation

The intent of the strategy initially proposed by Merck & Co. was to attenuate the potential toxicity risks associated with compounds capable of eliciting both the direct *and* idiosyncratic forms of reactive-intermediate-mediated liver toxicities. This was achieved by measuring the extent of the bioactivation process *in vitro* (covalent binding studies) in a variety of preparations (liver microsomes and hepatocytes from preclinical species and human to account for the full range of metabolic reactions and potential species differences in metabolism) and to elucidate the chemical mechanism by which bioactivation occurred. This latter process was facilitated by the use of chemical trapping agents, which enabled stabilization of otherwise highly reactive electrophilic species allowing their structures to be characterized and, thereafter, mechanisms postulated so as to infer how such species were initially formed. In so doing, lead chemical structures, otherwise already optimized for pharmacological potency *in vitro* and efficacy in preclinical studies were, in addition, optimized with respect to having minimal potential to form reactive intermediates. Covalent binding studies were also performed

in vivo in the rat in order to gain an understanding of how covalent binding observed *in vitro* in liver preparations translated into covalent binding observed in the liver homogenate and plasma of a whole animal following oral dosing. Other factors such as the anticipated dose level, the target population, and the severity of the disease were all additional considerations of this strategy—one which aimed to reduce metabolic activation in a systematic structure–reactivity mode of operation, but not one aimed necessarily at predicting toxicity since there are many other mediators of toxicity that are not dependent on drug bioactivation (e.g., inhibition of mitochondrial function, disruption of intracellular calcium homeostasis, activation of apoptosis, and inhibition of specific enzymes or transporters [58]), and it is known that covalent binding does not always track with toxicity. For these reasons, which are admittedly complex, the intent was for research groups to minimize covalent binding to <50 pmol drug equivalents per milligram protein, and to view this as a target threshold and not a “go” or “no-go” criteria. This value was chosen based on an ~20-fold margin over a covalent binding level of ~1 nmol drug equivalents per milligram liver protein associated with some model hepatotoxins in rodents (e.g., APAP, bromobenzene, furosemide, or 4-ipomeanol). This value also corresponded to a level of radioactivity that was ~10 times that of the experimental background under normal conditions, and thus provided a suitable dynamic range for measurement of covalently bound drug–protein adducts. The approach of BMS in using a fluorescently tagged trapping agent (dGSH) highlights the trend to move away from routinely synthesizing numerous radiolabeled compounds to conduct covalent binding studies [59–63].

At the outset of formulating this strategy, it was known that some compounds bind covalently to proteins yet fail to cause tissue damage. In what has now become a hallmark study, Tirmenstein and Nelson [64] evaluated the hepatotoxicity of APAP (4'-hydroxyacetanilide) and its regioisomer 3'-hydroxyacetanilide (AMAP) in the mouse and determined that APAP was hepatotoxic whereas AMAP was not; this despite the electrophilic metabolite of AMAP (a substituted benzoquinone) providing similar levels of covalent binding to that of the reactive product of APAP oxidation (a quinoneimine derivative). This lack of concordance between covalent binding and toxicity led skeptics of the strategy proposed by Merck & Co. [10] to point out that, in adopting this strategy, a company could potentially “throw out” perfectly good compounds. Proponents of this strategy, however, highlight that they acknowledge this discordance but armed with the experimental tools and means to rapidly overcome such a potential liability; it is better to bring a compound forward for expensive, regulated, drug development studies that is optimized in all regard as a pharmaceutical but with limited potential to form reactive intermediates, even in the absence of truly understanding the actual toxicological risk associated with forming a drug–protein adduct. Indeed, the medicinal chemistry “tool set” used to overcome metabolic activation is essentially the same as that used to optimize structure–pharmacokinetic/pharmacodynamic relationships [11,14] and can be performed very rapidly. The intent of the strategy proposed by Merck & Co. could therefore be summarized by the following statements.

1. The focus of the strategy was on “minimizing” bioactivation and not on “predicting” toxicity. The supposition was that by reducing covalent binding to <50 pmol drug equivalents per milligram protein (or as low as reasonably possible) in a variety of metabolism vectors *in vitro* and *in vivo*, one would markedly attenuate the safety risk potentially associated with metabolic activation (see taranabant

example; see below). As a consequence, the origin of this target threshold of binding was clearly somewhat arbitrary, not least because it related *in vitro* binding to *in vivo* binding without any regard to kinetically modeling the correlation.

2. To account for those instances where the bioactivation of a particular chemotype was inextricably linked to its pharmacology, or where there was overlap between pharmacological structure–activity relationship and bioactivation-mediated structure–reactivity relationship, additional qualitative factors were used to assess safety risk. This qualitative approach was premised on the notion that predictive toxicology based on covalent binding studies was not considered at the time to be feasible, not least because the APAP/AMAP example (see above) had shown this to be the case. When needing to undertake qualitative estimates of safety risk, however, this group did leverage *in vivo* parameters (e.g., estimated dose level, metabolic routes) when assessing covalent binding derived from *in vivo* studies, and metabolic turnover (e.g., extent and routes) when assessing *in vitro* covalent binding [65]; indeed such efforts generally date back to the 1990s [66]. Recently, more stringent attempts have been made to leverage covalent binding data to *predict* hepatotoxicity and the relative merits of these approaches are discussed (see above).
3. The strategy acknowledged that some compounds bind covalently to proteins, yet fail to cause tissue damage. This is probably attributable to multiple factors, which include:
 - a. Subcellular targets for adduct formation are different [67]. The binding of “critical” proteins will disrupt cell function, but the binding of “noncritical” proteins will not. A web site now exists (http://tpdb.medchem.ku.edu:8080/protein_database/) that catalogs the known protein targets of reactive intermediates for 18 well-studied chemicals and drugs of known toxicity [68], but the challenge still remains to discern which proteins, when disrupted, represent robust prognostics of cell function and potential downstream toxicity. Of note, to create an effective immunogen, an adducted protein of >50 kDa is considered to be required.
 - b. Protein adducts may differ in their “signaling” of an electrophilic insult, and recruitment of appropriate cellular defenses.
 - c. Some covalent binding may represent a detoxification or cytoprotective process. For instance, in mice dosed with APAP, GSH levels decreased 60% before serum-derived acetaminophen-cysteine (APAP-Cys; derived from enzyme-hydrolyzed serum protein) adducts were detected. In APAP overdose patients, serum-derived APAP-Cys adducts were detectable before large increases in prototypic liver function tests were observed [69].
 - d. Some drug–protein adducts may differ in their stability. The stability or persistence of a drug–protein adduct may be a critical determinant of toxicity. Studies with model electrophile probes have indicated that instability of an adduct corresponded with lack of toxicity *in vitro* [70].
4. Covalent binding is a quantitative measure of the bioactivation process and only provides an assessment of reactivity of the putative reactive intermediate toward a protein nucleophile.
 - a. When the parent drug is radiolabeled, one can assess the potential to form drug–protein adducts *in vivo* and *in vitro*.

- b. When covalent binding studies are conducted with chemical trapping agents, such studies serve the dual purpose of providing a quantitative estimate of the amount of adduct formed (e.g., by using a fluorometric assay to monitor adducts that react with dansyl glutathione (dGSH) [71] or monitoring radioactive levels of adduct formed with ^{35}S -GSH [72] or ^{14}C -cyanide [73]), and access to products that lend themselves to characterization (notably by mass spectrometry) as the precursor step for defining the mechanism by which bioactivation has occurred. This underpins a considered chemistry strategy to overcome reactive intermediate formation.
5. In isolation, covalent binding is a measure of bioactivation, not a predictor of toxicity. Of note, liver microsomes are “CYP450 rich” and represent an ideal model system to exacerbate metabolic phase I bioactivation reactions and in which to chemically trap reactive intermediates for subsequent characterization. Attenuation of metabolic activation in liver microsomes, therefore, represents a high stringency hurdle for medicinal chemists.

The following projects represent examples where metabolic activation has been overcome as part of pharmaceutical lead structure optimization. The important distinction is that for both the taranabant and the selective estrogen receptor modulator (SERM) examples, covalent binding was reduced as a part of drug optimization *without* any toxicology studies having yet initiated. This approach by Merck & Co. was premised on the fact that it is not possible to predict *a priori* whether a drug candidate that undergoes metabolic activation will cause toxicity in animals or humans. Moreover, even if a drug candidate undergoes metabolic activation, but fails to cause tissue damage during preclinical safety assessment, there remains the concern that it may elicit immune-mediated adverse events in humans (idiosyncratic toxicity, see above). This is a concern since no animal model exists for human immune-mediated toxicities, the clinical incidence of immune-mediated adverse events is vanishingly small, and hence safety issues are identified only after the patient population has become relatively large (phase 3 clinical trials and beyond), a time by which significant financial investment has already been made in the product. Indeed, this proactive approach to mitigating metabolic activation has been widely adopted by both the pharmaceutical industry and academia and representative, although by no means exhaustive, examples of this are presented in Table 5.3 [74–92] to demonstrate the broad-based adoption of this strategy across a wide range of therapeutic areas. This approach is undoubtedly related to the recognized deficiencies using preclinical species to predict clinical hepatotoxicity [5]. This is exemplified by a cross-pharmaceutical company retrospective review of candidate drugs in clinical development where 31/238 (14%) cases of hepatotoxicity were observed. Of these 31 compounds, 13 (42%) were negative in preclinical safety studies and 18 (58%) were positive, and this led to 14 compounds (45%) being terminated and 17 compounds (55%) continuing in clinical development [93]. Since compounds continued in clinical development, despite toxicity in preclinical studies, highlights the medical benefit–risk management process evident in all pharmaceutical companies. The fact that drug withdrawals have occurred as a consequence of drug-induced idiosyncratic hepatotoxicity, or clinical drug development has been stopped as a consequence of liver toxicity being observed in man, but not in preclinical species, highlights the limitations of animals as models of human toxicity mechanisms. The remaining two examples discussed, those of optimizing either a leukotriene- or an $\text{A}_{2\text{A}}/\text{A}_1$ -receptor

TABLE 5.3 Reducing Potential for Metabolic Activation as a Consideration During Drug Design

Structures	Therapeutic Area, Observation, and Outcome
	HIV (NNRTI, Pfizer): Speculated that 3-methyl-indazole could undergo proton abstraction from the methyl followed by single electron oxidation to form the imine methide. The 3-ethyl-analog was stable to reactive intermediate formation [74]
	HIV (NNRTI, Pfizer): Capravirine analog. Reactive metabolites trapped (GSH) but no further reports yet published [75]
	HIV (Integrase inhibitor, Merck & Co.): Dihydropyridopyrazine-1,6-dione series optimized for reduced covalent binding: (<50 pmol drug equivalents/mg protein/60 min incubation in rat and human liver microsomes; <5 pmol drug equivalents/mg protein in rat liver homogenate <i>ex vivo</i> [76]):
	Pain (Bradykinin B1 receptor antagonist, Merck & Co.): 2,3-Diaminopyridine (2,3-DAP) analogs were determined to be CYP3A metabolism dependent inhibitors and were also shown to extensively bind to rat and human liver microsomes (2–4 nmol drug equivalents/mg protein/60 min). Oxidation of the 2-amino group produced the highly electrophilic species, pyridine-2,3-diimine, which led to the discontinuation of this series [77,78]
	Neurodegenerative disorders, including Parkinson's and Huntington's diseases (A _{2A} receptor antagonist, Neurocrine Bioscience & Amirall Research): Concern for unsubstituted furan bioactivation led to methylation α to the furan oxygen (cf KW-6002) and bis-methyl substitution of the pyrazole moiety. This later change, in addition to replacement of the furan with a thiophene, was optimal for pharmacokinetics and pharmacodynamics [79]

(continued overleaf)

TABLE 5.3 (Continued)

Structures	Therapeutic Area, Observation, and Outcome
	Cancer (OSI Pharmaceuticals): OSI-930 is well tolerated and efficacious in animal models and humans. GS-conjugates was consistent with thiophene bioactivation (S-oxidation to the sulfoxide). Given the severity of the therapeutic indication and the finding that a radiolabeled close was cleared from rat tissue with a half-life of 1–1.5 days, this bioactivation was not considered, in isolation, to be a major concern [80]
	Cancer & Stroke (Selective gelatinase inhibitor, University of Notre Dame, IN, USA): GS-conjugates were characterized for SB-3CT indicating that the thiirane ring had undergone bioactivation. Methyl-substituted analogs were investigated to attenuate bioactivation [81]
	Angiogenesis (Vascular endothelial growth factor-2 tyrosine kinase (VEGF) inhibitor, Amgen): This cyclopropylamide analog provided levels of covalent binding <i>in vitro</i> (human liver microsomes) of ~350 pmol drug equivalents/mg protein/60 min. The unsubstituted naphthamide had markedly attenuated levels of covalent binding (<40 pmol drug equivalents/mg protein/60 min) with retained pharmacokinetic and pharmacodynamic properties [82]
	Inflammation, including arthritis (FMS inhibitor, Janssen Research & Development): Potential to form quinonediimine type reactive intermediates led this group to (i) replace the methylpiperazine moiety with a C-linked piperidine and (ii) replace the N-linked piperidine with a cycloalkene substituent. Pharmacokinetic and pharmacodynamic properties were commensurately optimized [83]

TABLE 5.3 (Continued)

Structures	Therapeutic Area, Observation, and Outcome
	Migraine (KCNQ2 potassium channel opener, Bristol-Myers Squibb): When R=H, reactive metabolites were formed that were also implicated in the metabolism dependent inhibition of CYP3A. When R=F, CYP3A inhibition was overcome. Only F-substitution adjacent to the morpholinyl moiety significantly reduced CYP3A inhibition, indicating that CYP450 inhibition was attributable to formation of quinoneimine- and/or quinonemethide-type intermediates [84]
	Seasonal allergic rhinitis (Prostaglandin D ₂ receptor (PGD ₂) antagonist, Merck & Co.): MK-0524 was the product of optimizing earlier lead structures that formed an iminium cation. The methylsulfone in MK-0524 was postulated to destabilize the putative iminium cation due to its powerful electron withdrawing properties [85,86]
	Cancer (cMet, a receptor tyrosine kinase inhibitor, Amgen): For AMG-458, the O-aryl moiety was observed to be displaced, forming a methoxyquinoline GS-conjugate. Replacement of O with N as the linker virtually eliminated any detectable adducts. Substituents that interfered with oxygen lone pair delocalization to the aromatic system, thereby reducing potential of the alkyl substituent to serve as a leaving group, also reduced potential for GS-adduct formation [87]
	Breast cancer (SERM, University of Illinois, USA): 4'-Fluoro-desmethylarzoxifene (4'-DMA) exemplifies how 4'-fluorination resulted in a marked reduction of oxidative bioactivation to quinone-type products [88–90]

(continued overleaf)

TABLE 5.3 (Continued)

Structures	Therapeutic Area, Observation, and Outcome
	Pain (NR2B-selective antagonist, Pfizer): Phenol bioactivation was observed for CP-101,606 with commensurate formation of quinone-type products. Various phenol bioisosteres were evaluated and a pyrazole substituent was determined to be a successful replacement [91]
	Pain (Neuroscience Center of Excellence, Louisiana State University Health Center, LA, USA): Efforts were made by this group to attenuate metabolic activation and optimize the general safety profile of APAP. The 3-oxo-1,2-benzisothiazol-2-yl-1,1,-dioxide acetamide analog was evaluated in limited acute toxicity studies and demonstrated an improved liver function test profile in mice [92]

antagonist, represent a response to an *observed* toxicity, but nevertheless used the same tool box (understand the chemical mechanism of bioactivation by chemically trapping reactive intermediates and thereafter mitigate against this biotransformation) to overcome their respective structural deficits and provide a successful outcome for the project.

5.2.1.1 Optimization of Taranabant. During the discovery of taranabant (MK-0364, Table 5.4), a novel acyclic amide cannabinoid-1 inverse receptor agonist (CB1R) that was formerly in clinical development as a low dose (<10 mg once daily) compound for the treatment of obesity [94–97], reactive intermediate formation was attenuated using a structure–reactivity approach deployed across a series of closely related chemical analogs. While in this study radiolabeled analogs were prepared using a common tritiated precursor (which expedited the time lines of these studies), it might be expected that the use of dGSH [71] will also have produced similar rank order data for the extent of metabolic activation observed. During the optimization of this aryloxy series of compounds, sites of metabolic activation were identified rapidly using online LC-MSⁿ on an ion trap mass spectrometer. Following incubation of the initial phenyl analog with rat or human liver microsomes, reactive intermediates were trapped as their corresponding glutathione conjugates. Mass spectral characterization of these conjugates allowed potential sites and mechanisms of bioactivation for this compound to be proposed (phenyl oxidation → *ortho*-quinone). One strategy to reduce metabolic activation was to explore aromatic fluorine substitution as a means of blocking sites of oxidative metabolism, the aim being to take advantage of the electron-withdrawing effects of fluorine to reduce the π -electron density of the aromatic ring and hence render this moiety less susceptible to CYP450 catalyzed metabolism [98,99]. In addition, the carbon–fluorine bond is stronger than the corresponding carbon–hydrogen bond, and thus is less prone to oxidative cleavage. Unfortunately, fluorinated analogs, such as the 3,5-diF-phenyl derivative, underwent extensive metabolic activation that

TABLE 5.4 Optimization of Taranabant (MK-0364): Irreversible Binding of Radioactivity to Human and Rat Liver Microsomal Protein upon Incubation with a Series of Tritiated CB1R Inverse Agonists at a 10 μ M Concentration for 1 h in the Presence of an NADPH-Regenerating System

X	Ar	Covalent Binding to Liver Microsomal Protein ^a (pmol drug equivalents/mg protein)

The irreversible binding was assessed both in the absence and presence of 5 mM GSH.

^aTritium was incorporated in to the bi-phenyl moiety of the molecule.

was accompanied by oxidative dehalogenation and formation of glutathione adducts. Therefore, an alternative strategy was pursued whereby a pyridine was incorporated as a phenyl isostere replacement; this modification resulted in reduced levels of metabolic activation. Further improvements were made via chlorination (5-Cl-2-pyridine-analog) or trifluoromethylation (5-CF₃-2-pyridine-analog) of the pyridine. Additional structural refinements in other parts of the molecule (nitrile analog; taranabant) provided a compound with minimal bioactivation properties, while retaining desirable pharmacokinetic and pharmacodynamic characteristics. The clinical use of centrally acting CB1R inverse agonist has, however, stopped because of unacceptable central side effects for this class of compound [100].

5.2.1.2 Optimization of a SERM. A similar approach was taken in optimizing a SERM, a class of compound that treats breast cancer and postmenopausal symptoms, where the initial tritiated lead was determined to covalently bind to proteins in a time- and NADPH-dependent manner following incubation with human liver microsomes (1100 pmol drug equivalents per milligram protein) [101] (Fig. 5.2). At least three bioactivation pathways were determined and included oxidative cleavage of the dihydrobenzoxathiin moiety to give a hydroquinone/*para*-benzoquinone redox couple, hydroxylation at position 5 or 7 of the benzoxathiin moiety leading to an *ortho*-quinone intermediate, and metabolism of the piperidine ring to give an iminium ion. The latter reactive intermediate was identified as its bis-cyano adduct when sodium cyanide was included in the incubation mixture as a reactive intermediate trapping agent. Structural

Figure 5.2 Optimization of a SERM.

modification of **I**, including a replacement of the piperidine with a pyrrolidine group, led to **II**, which did not form a reactive iminium ion. Following the incubation of **II** with human liver microsomes, covalent binding was reduced to 450 pmol drug equivalents per milligram protein. When covalent binding studies were conducted using human hepatocyte preparations, the level of binding for **I** and **II** was 170 and 50 pmol drug equivalents/mg protein, respectively, again highlighting how structure-covalent binding optimization of a series of compound was achieved with a good understanding of the bioactivation mechanism.

5.2.1.3 Optimization of a Leukotriene Receptor Antagonist. The development of CP-85,958 was discontinued because of liver toxicity in monkeys [102]. The underlying mechanism of toxicity was considered to be related to the formation of the lactol that could ring open to produce a reactive hydroxy-aldehyde intermediate capable of alkylating endogenous proteins (Fig. 5.3). Subsequent chemical modifications to CP-85,958 involved methylation at the 2-position to block lactol formation, chiral resolution to give the dextrorotatory enantiomer, and replacement of the carboxylic acid with a trifluoromethylsulfonamide to afford CP-195,494. This compound was pharmacologically active in animal models and had the same order of potency as zafirlukast and pranlukast and was an order of magnitude more potent than its predecessor, CP-85,958. An alternative approach to optimizing CP-85,958 was also investigated and involved introducing chemical groups that increased both pharmacological potency and metabolic lability at a site other than that leading to lactol formation [103]. The pharmacokinetics of these alternative compounds, CP-199,330 and CP-199,331, were investigated in rats and monkeys, with CP-199,331 having the better profile (low clearance, moderate half-life, 8–10 h, and good oral bioavailability, 46–72%). For both compounds, O-demethylation to the corresponding phenol was the major metabolite observed, thereby providing some evidence of metabolic switching away from formation of the lactol. When dosed to monkeys for five days, no liver toxicity was observed at plasma concentrations in excess of an order of magnitude higher than those predicted for clinical efficacy.

5.2.1.4 Optimization of a Dual A_{2A}/A_1 Receptor Antagonist. JNJ-27631734 (Fig. 5.4) is an A_{2A}/A_1 receptor antagonist and represented a lead compound being considered for development as a potential treatment for Parkinson's disease [104]. When assessed in the standard battery of genotoxicity assays, it was shown to be Ames positive in the *Salmonella typhimurium* strain TA1537, but only after the activation by induced (aroclor 1254) rat liver S9, indicating a role of metabolism in

Figure 5.3 Optimization of a leukotriene receptor antagonist.

the positive genotoxicity outcome. The compound was similarly positive in the mouse lymphoma assay, again only in the presence of induced rat liver S9. Experiments in which sodium cyanide was used to trap putative reactive intermediates in the presence of either induced rat liver S9 or human liver microsome preparations were conducted and yielded comparable qualitative and quantitative results indicating that in both species *in vitro*, the pyrrolidine group had undergone sequential two-electron oxidations to form iminium ion intermediates as precursors of a bis-cyano final product. A test compound whereby the two carbon atoms α to the pyrrolidine nitrogen were substituted with methyl groups did not form cyano adducts and were shown to be Ames negative providing evidence that pyrrolidine activation had been a key bioactivation step for genotoxicity. Further optimization of the compound (pyrrolidine $\rightarrow$ pyridine) yielded a product that was optimized for potency, efficacy, pharmacokinetic properties, and lack of genotoxicity.

Notwithstanding the fact that there is much information in the scientific literature to increase the awareness of medicinal chemists to chemical structure alerts prone

Figure 5.4 Optimization of an A_{2A}/A₁ receptor antagonist.

to metabolic activation [105–107], the foregoing examples indicate that the simple structure modifications can attenuate metabolic activation while maintaining or improving the pharmacokinetic and pharmacodynamic properties of the compound [11] and include

- isostere replacements—for example, pyridine for phenol
- metabolic blocking/steric hindrance—for example, introduction of a methyl group
- metabolic switching—for example, introduction of a methoxy moiety
- electronic effects—for example, phenyl substitution with fluorine.

5.2.2 Evaluation of Covalent Binding as a Component of Predicting Hepatotoxicity

The role of covalent binding studies, whether using liver protein to trap radiolabeled drug-related material or nucleophilic “trapping agents” (labeled or not) to trap drug-related reactive intermediates, have been used effectively to reduce the extent of metabolic activation during lead structure optimization. Recently, however, efforts have been made to leverage these data as a part of an integrated approach to *predict* the risk of developing hepatotoxicity. A number of groups have done this, notably Roche, AstraZeneca (data not shown), BMS, Pfizer, and Daiichi Sankyo (see below) where the learning is that prediction of hepatotoxic risk is improved when one integrates the amount of bioactivation derived from covalent binding studies with an understanding of how much exposure there is to the reactive intermediate, which is a function of inputs such as metabolic turnover *in vitro* and the daily dose level encountered in the clinic. In recent years, these more integrated approaches have been more widely investigated by the industry and are now presented in greater detail, notwithstanding the recognized limitations of this approach.

Researchers at Pfizer performed a retrospective investigation of whether integrating covalent binding data with pharmacokinetic data *in vitro* (intrinsic clearance, CL_{int}) and *in vivo* (pharmacologically effective human dose) could distinguish between known clinical hepatotoxins and nonhepatotoxins. This group evaluated a quantitative approach to derive a hypothetical estimate of “total daily dose of covalent binding” equivalents (Dcb; mg/day) for 18 radiolabeled compounds (9 known hepatotoxins and 9 nonhepatotoxins) in human liver microsomes [108] or cryopreserved human hepatocytes [109], where Dcb in this latter metabolic system was defined as

$$Dcb = fCL_{cb} \cdot \text{daily dose}$$

in which fCL_{cb} is the fraction of metabolism comprised by covalent binding,

$$fCL_{cb} = \frac{CL_{int, cb}}{CL_{int} + CL_{int, cb}}$$

and CL_{int} is the intrinsic clearance obtained using cryopreserved human hepatocytes:

$$CL_{int} = \left(\frac{[S]}{AUC} \right) \cdot \left(\frac{V}{\text{Number of cells}} \right)$$

where $[S]$ was the initial substrate concentration, V is the incubation volume, and AUC is the area under the $[S]$ versus time curve.

The level of covalent binding for these 18 compounds to *human liver microsomes* was determined not to be discriminatory with respect to their classification as either a hepatotoxin or nonhepatotoxin [108]. Indeed, seven of the nine nonhepatotoxic drugs demonstrated binding to liver microsomes. However, when a Dcb cutoff value of 1 mg/day was used, as determined using *human hepatocyte* preparations, 6 of 9 hepatotoxins (67%) were correctly categorized as having Dcb > 1 mg/day (exceptions were hepatotoxins sudoxicam, felbamate, and CBZ, which had Dcb < 1 mg/day), and 12 of 17 (71%) compounds were correctly categorized as either nonhepatotoxins or hepatotoxins (the additional exceptions were the nonhepatotoxins buspirone and propranolol, which had Dcb values > 1 mg/day) [109].

Similarly, researchers at BMS evaluated dGSH as a trapping agent to quantify adduct formation following the incubation of 50 drugs (10 associated with toxicity, 40 that were not) in *human liver microsomes* [110]. Unlike covalent binding studies with radiolabeled drug that will provide information on the capability of all types of reactive intermediate to bind to liver macromolecules, the use of dGSH is more restrictive and typically will not provide stable conjugates with, for example, “hard” electrophiles such as iminium ions. Nevertheless, the use of a dansylated chemical trapping agent does allow for both downstream chemical characterization of the precursor-reactive intermediate (allowing a plausible bioactivation mechanism to be postulated) and for relatively high throughput fluorescence and UV quantification of adducts formed relative to the overall turnover of the compound (f_m). Similar to the Pfizer group, BMS also used known human pharmacokinetic values, notably dose level (D), fraction of dose absorbed (f_a), and fractional clearance via oxidative metabolism (f_m) to provide an integrated assessment of approximate daily burden of thiol-reactive metabolites (D_{rm}):

$$D_{rm} = D \cdot f_a \cdot f_m \cdot f_{rm}$$

When focusing only on the percentage of thiol adducts formed (as would be the case during lead optimization), a number of “safe” drugs formed adducts (including paroxetine, losartan, montelukast, raloxifene, omeprazole, and lansoprazole). Conversely, a number of “toxic” drugs did not form adducts (including CBZ, flutamide, phenytoin, terbinafine, and zileuton) reinforcing the limitation of using such data as stand-alone criterion for decision making. However, when using the more integrated approach described for D_{rm} , nonhepatotoxic drugs (risperidone, simvastatin, rosiglitazone, paroxetine, losartan, and raloxifene) and hepatotoxic drugs (acetaminophen, clozapine, and troglitazone) were separated with D_{rm} values of less or greater than 10 mg, respectively, highlighting the predictive merit of this approach. Intermediate values of D_{rm} (1–10 mg) were obtained for one nonhepatotoxic drug (duloxetine) and two hepatotoxic drugs (diclofenac and nimesulide). At BMS, no absolute threshold is set for compound rejection, although for compounds projected to be administered at relatively high doses, <1% (~1000 pmol thiol adduct/h/mg protein) of adduct formation is deemed acceptable as long as there is reasonable metabolic turnover of the compound. Follow-up studies to assess reactive intermediate formation *in vivo*, representing a fully integrated biological system, are also performed regularly. As for other companies, BMS will rarely use covalent binding data as stand-alone criteria for stopping the progression of a candidate compound; they instead preferring to view these data as only one part of overall risk assessment.

Researchers at Daiichi Sankyo have also expended considerable effort in understanding the value of covalent binding studies as predictors of toxicity. Takakusa *et al.* [111] initially investigated 16 drugs that were associated with a variety of toxicities (hepatotoxicity, agranulocytosis, or hypersensitivity reactions) that either carry a Black Box warning, or have been removed from the market, and assessed their covalent binding in protocols initially proposed by researchers at Merck & Co. [10,112]. Daiichi Sankyo also assessed four “safe” drugs such as amlodipine, caffeine, valsartan, and warfarin (Table 5.5). This group chose compounds based on the diversity of the reactive intermediates implicated in their toxicities, and included quinoneimine derived from amodiaquine [113], *ortho*-quinone from benzbromarone [114], quinone-methide from tacrine [115], nitrenium ion from clozapine [116], iminium ion from nevirapine [105] and zafirlukast [117], nitroso species from erythromycin [118], phenacetin [119], procainamide [120] and sulfamethoxazole [121], arene oxide for imipramine [122], acyl glucuronide for valproic acid [123] and zomepirac [124], and radical species from aminopyrine [125], flutamide [126], and phenytoin [127]. While values of covalent binding in rat and human liver microsomes for the “safe” drugs were all <50 pmol drug equivalent/mg protein, values of covalent binding in human liver microsomes were determined to be a poor predictor of toxicity for “withdrawn” drugs (aminopyrine and zomepirac) and Black Box drugs (clozapine, nevirapine, and valproic acid), since they also provided levels of covalent binding of <50 pmol drug equivalents/mg protein. However, most (seven of eight) of the drugs in the withdrawn or Black Box warning category exhibited levels of covalent binding higher than 50 pmol drug equivalents/mg protein when assessed collectively in the *in vitro* assay performed using human liver microsomes and in the rat *in vivo* assay providing some basis for a reasonable risk assessment. Of note, long term retention of radioactivity in the bone marrow of rats was observed for some drugs associated with severe agranulocytosis (e.g., amodiaquine and clozapine), possibly as a consequence of drug-related material binding to stromal cells in the bone marrow [111]. The same research group progressed to assessing the covalent binding potential of a broader range of drugs in three test systems; namely, human liver microsomes, human hepatocytes, and *in vivo* in rat liver [128]. While covalent binding in either of the test systems were in of themselves not predictive of human toxicity, Nakayama *et al.* [128] did propose a “zone classification system” where 30 of the 37 drugs tested were correctly assigned to their respective safety categories where covalent binding in human hepatocyte preparations adjusted for daily dose was the best predictor among the three test systems evaluated.

Overall, there appears a good opportunity during early stage drug structure optimization to use trapping agents to direct medicinal chemistry efforts toward compounds with reduced potential for metabolic activation without the need to necessarily synthesize numerous radiolabeled compounds—this has been the approach at Janssen Research & Development. Once a lead compound emerges, however, certainly if it still carries some bioactivation risk, synthesis of a radiolabeled analog and evaluation of its bioactivation potential in a variety of protocols (*in vivo* and *in vitro*) do have merit as part of an integrated risk assessment toward defining organ toxicity risk. Covalent binding studies performed in hepatocyte preparations, with adjustment of derived data for metabolic turnover and anticipated daily dose level, appear to increase the ability to predict risk of a hepatotoxicity outcome.

TABLE 5.5 Covalent Binding Data for Black-Box and Withdrawn Drugs or Drugs Associated with Hepatotoxicity or Hypersensitivity Reactions

	Daily Dose (mg)	CB <i>In vitro</i> (+NADPH) ^a (pmol equivalent/mg protein)		CB <i>In Vivo</i> (pmol equivalent/mg protein)	
		RLM	HLM	Liver	Plasma
<i>Withdrawn or Black-Box</i>					
Aminopyrine (W)	130–3000	26	54	560	790
Amodiaquine (W) ^b	1750–2450	258	94	130	4

5.2.3 Covalent Binding Data as Part of an Integrated Risk Assessment

In the foregoing examples of covalent binding studies conducted by Pfizer and BMS, there were outlier results in the context that some drugs were purposefully included in the study as examples of being “safe” or “nonhepatotoxic” yet were not classified correctly. The examples included propranolol, buspirone, paroxetine, and raloxifene. Conversely, there were also drugs evaluated that were examples of being “not safe” or “hepatotoxic” yet were incorrectly categorized as “safe” and included CBZ, phenytoin, felbamate, and sudoxicam. These examples are discussed from the viewpoint of points to consider when integrating data from several sources as part of the aforementioned risk assessment, as would be the case during lead selection, but helps also in highlighting the deficiencies that still exist with respect to predictive hepatotoxicology.

5.2.3.1 Propranolol. Innopran; daily dose 160–480 mg [128]; Dcb > 1 mg/day in cryopreserved human hepatocytes [109], Fig. 5.5.

Propranolol is widely used for the treatment of hypertension or arrhythmias as an adrenoceptor blocking agent. While classified by Nakayama *et al.* [128] as a drug without a Black Box warning but with a warning for hypersensitivity reactions and agranulocytosis, propranolol is generally regarded as having an excellent clinical safety record and was defined as a prototypic nonhepatotoxin in the Pfizer study [109]. In rat, it was reported that 4-hydroxy metabolite can generate 1,4-naphthoquinone (trapped with GSH), which can potentially inactivate rat CYP2D and covalently bind to proteins present in rat liver microsomal preparations [129]. Propranolol 4-hydroxylation is controlled by polymorphic CYP2D6 in humans and the same downstream quinone reactive intermediate pathway is considered to be relevant in rats and humans as being implicated in CYP2D inactivation [130]. Nakayama *et al.* [128] derived levels of covalent binding (pmol drug equivalents/mg protein) for propranolol, which were 70 (human liver microsomes), 9 (human hepatocytes), and 87 (rat liver homogenate *ex vivo*) highlighting potential for competing phase 2 metabolic conjugation reactions to attenuate the level of binding in human hepatocytes relative to human liver microsomes. This

Figure 5.5 Structures of compounds that were not classified correctly as either hepatotoxins or nonhepatotoxins in covalent binding studies.

was also supported by the attenuation of covalent binding in human liver microsomes to which UGT cofactors had been added [108], and borne out, albeit post hoc in the context of a discussion occurring during lead drug optimization or a final decision as a development candidate, by the observation that 17% of the drug undergoes direct glucuronidation in humans [131]. The negative side of the risk assessment is the potentially high daily dose and a well-defined mechanism of bioactivation that translates to measurable covalent binding *in vitro* and *in vivo*. The importance of alternative (non-bioactivating) metabolic pathways, notably glucuronidation, typically does weigh high when attempting to assess hepatotoxicity risk and is presumably why, at least in part, propranolol turned out to have such a good clinical safety record. Overall, however, the integrated classification approach proposed by both Pfizer and Daiichi Sankyo consistently categorized propranolol as a potential hepatotoxicant (a false positive), highlighting the fallible nature of this predictive exercise.

5.2.3.2 Buspirone. BuSpar; daily dose 60 mg; Dcb > 1 mg/day in cryopreserved human hepatocytes [109], Fig. 5.5.

Buspirone is used to treat anxiety disorders and is considered to have a good clinical liver safety record. The Pfizer group also investigated related analogs, nefazodone (Serzone; daily dose 200–400 mg typical, 600 mg encountered, [132]) and aripiprazole (Abilify; daily dose 10–30 mg [133]), with a view to rationalizing their potential to mediate toxicity based on their bioactivation potential, covalent binding in liver microsome preparations and cryopreserved hepatocytes, and general pharmacokinetic properties. Nefazodone was withdrawn from the market by the manufacturer in 2003 [134] when the marketing company acknowledged a worldwide total of 28 reports of liver failure resulting in 18 deaths [135–137]. Since this time, research efforts have focused on the effects of nefazodone on drug transporter and mitochondrial function, as well as investigating its potential to undergo metabolic activation to gain a mechanistic understanding of its toxicity. Kostrubsky *et al.* [138] reported that nefazodone caused strong inhibition of the human bile salt export pump (BSEP) in human hepatocyte preparations and that transient increases in bile acids were detected in rat serum following oral dosing. Buspirone did not exhibit such effect on the bile acid transport system in this study. Similarly, nefazodone was determined to strongly inhibit mitochondrial function *in vitro*, whereas buspirone showed minimal toxicity [139]. Regarding potential for metabolic activation, the CYP3A4-mediated 4-hydroxylation of the 3-chlorophenyl-piperazinyl moiety in nefazodone, and the subsequent two-electron oxidation of this product to a quinoneimine reactive intermediate, was speculated to be involved in the etiology of liver toxicity in humans. Buspirone contains a pyrimidine ring in place of the 3-chlorophenyl moiety and while it also undergoes 4-hydroxylation, no glutathione conjugate of a putative downstream analogous quinoneimine reactive metabolite was detected, although the experimental finding of Dcb > 1 mg/day supports a conclusion that a bioactivation event has occurred but not yet mechanistically characterized. These researchers rationalized that a two-electron oxidation of *para*-hydroxybuspirone was less energetically favorable than that of *para*-hydroxynefazodone [132]. Similarly for aripiprazole (Abilify), a compound with a good safety profile, the 2,3-dichlorophenyl-piperazinyl moiety can undergo *para*-hydroxylation, but no further aberrant metabolism of this product was observed [133]. The conclusion from this line of investigation was that pyrimidinyl- and 2,3-dichlorophenyl-substituted piperazinyl analogs were preferable (“safer”) structural motifs compared to a 3-chlorophenylpiperazinyl moiety present

in nefazodone. On the negative side of the risk assessment, therefore, buspirone had $D_{cb} > 1$ mg/day. Conversely, buspirone had minimal potential to undergo “nefazodone-like” bioactivation, and demonstrated minimal potential to inhibit either BSEP or mitochondrial function.

5.2.3.3 *Paroxetine.* Paxil; daily dose 20 mg, Fig. 5.5.

Paroxetine, an antidepressant that contains a structure alert in the form of a 1,3-benzodioxole (methylenedioxyphenyl), provides high levels of covalent binding in liver microsomes [108] yet has been prescribed for over a decade, where life-threatening adverse drug reactions have been extremely rare [140,141]. Its bioactivation has been well characterized [142] (paroxetine $\rightarrow$ paroxetine catechol $\rightarrow$ two-electron oxidation to the *ortho*-quinone), which is consistent with its well-characterized and clinically relevant MBI of polymorphic CYP2D6. On the negative side of the risk assessment, therefore, there is evidence of MBI *in vitro*, a plausible mechanism of bioactivation, and significant levels of covalent binding in liver microsomal preparations. Conversely, the paroxetine catechol is efficiently conjugated during phase 2 metabolism (*O*-methyl, sulfate, and glucuronide conjugates have been identified) and the parent drug has a low daily dose (20 mg). Indeed, when integrating data on dose level and the fraction of metabolism in hepatocytes resulting in covalent binding, where phase 2 metabolism can be accommodated, the risk associated with metabolic activation for paroxetine was deemed minimal ($D_{cb} < 0.1$ mg/day [109]).

5.2.3.4 *Raloxifene.* Evista; daily dose 60 mg, Fig. 5.5.

Raloxifene is an SERM, which is effective in the treatment of osteoporosis in postmenopausal women. Overall, raloxifene has a good safety record in the clinic albeit for a case of hepatitis in a 49-year-old woman who had jaundice accompanied by elevated liver enzymes following oral administration of the drug for 30 days [143]. The toxicity was suggested to result from an immune mechanism based on observations of skin rash and eosinophilia [144], but the role of chemically reactive metabolites of raloxifene in the process remains unknown. When incubated with human liver microsome preparations, raloxifene elicits high levels of covalent binding [108,110]. Glutathione adducts of raloxifene have been identified in such preparations; substitution with GSH occurring at the 5- or 7-position of the benzothiophene moiety or at the 3'-position of the phenol ring, with the 7-glutathionyl derivative being most abundant based on LC/MS and NMR (nuclear magnetic resonance) analyses. These adducts are postulated to derive from addition of GSH to raloxifene arene oxides followed by dehydration and aromatization. Alternatively, raloxifene may be oxidized to an extended quinone intermediate, which is then trapped by GSH conjugation. The bioactivation of raloxifene is catalyzed by CYP 3A4 [145]. To balance these negative properties, an inspection of the chemical structure of raloxifene highlights two phenol moieties (potential to form 6- β - and 4'- β -glucuronides), which are likely to be available for metabolic phase 2 conjugation. Indeed, in cryopreserved human hepatocytes, the level of covalent binding was markedly attenuated ($D_{cb} < 1$ mg/day) [109]. What would not be known at the preclinical stage of development is the actual dose level or the expected degree of first pass glucuronidation. As determined post hoc, the dose turned out to be relatively low (60 mg) and the extent of intestinal first pass glucuronidation turned out to be extremely high, accounting for 95% of the dose [146]. What was known preclinically, however, was that biliary clearance of phenolic glucuronide conjugates of raloxifene

in the rat was high (~50%) [147], and the level of covalent binding in cryopreserved human hepatocytes was low [109] which, coupled to an understanding of metabolic routes *in vitro* (preclinical species vs human), would have helped rationally ameliorate the concern over the observed high levels of covalent binding observed in liver microsome preparations (Dcb > 1 mg/day) [108].

5.2.3.5 *Sudoxicam*. Daily dose 50 mg, Fig. 5.5.

Sudoxicam is a nonsteroidal anti-inflammatory that exerts its pharmacological action via cyclooxygenase inhibition but has been associated with cases of severe hepatotoxicity resulting in its withdrawal from clinical use [148]. Despite this, sudoxicam was shown to be indistinguishable from meloxicam, a nonhepatotoxin with a good safety record (daily dose, 15 mg), in regard to derived covalent binding observed following incubation in human hepatocyte preparations (Dcb values of “zero” [109]). This result is quite striking given that meloxicam differs from the structure of sudoxicam in only a 5'-methyl substituent on the thiazole ring. The Pfizer group speculated that this methyl substituent represents a metabolic “soft spot,” undergoing oxidation to 5'-hydroxymethyl and 5'-carboxy products as major products of metabolism in human and preclinical species [149], rather than is the case for sudoxicam where thiazole C4-C5 epoxidation is a major route of metabolism, relative to total metabolism, ultimately leading to ring scission and generation of the acylthiourea product [150]. This product can undergo S-oxidation to reactive sulfenic or sulfinic acid intermediates that can adduct to endogenous proteins leading to toxicity [151]. Despite this mechanistic rationale, it remains that sudoxicam was not effectively highlighted as a hepatotoxin by covalent binding methodologies alone. While the dose level of sudoxicam is approximately fourfold higher than meloxicam, and the identity of the proteins adducted by sudoxicam may be very relevant to its toxicity, these represent two parameters that are not easily accessible during decision making in early phase lead optimization. As such, sudoxicam represents a false negative outcome in these investigations.

5.2.3.6 *Antiepileptics—Felbamate, Carbamazepine, and Phenytoin*. Felbamate is typically used at very high doses (600 mg, titrated to 3600 mg daily) and its use was restricted via a Black Box warning due to 34 cases of aplastic anemia that resulted in 13 deaths, and 23 cases of hepatic failure that resulted in 5 deaths. The metabolism of felbamate is well understood and is characterized by the esterase-mediated formation of the monocarbamate, which can then be metabolized further by alcohol dehydrogenase to the aldehyde carbamate (Fig. 5.6) [152–154]. In a competing pathway to that leading to either the acid carbamate or the cyclic carbamate, the aldehyde carbamate can undergo β -elimination to afford the α,β -unsaturated aldehyde (2-phenylpropenal), a highly reactive electrophilic species. The lack of toxicity of felbamate in rats relative to humans was suggested to be related to the finding that only a third as much felbamate is converted to the monocarbamate in rats compared to humans, which translates to mercapturate levels of felbamate metabolites in humans being approximately sixfold higher than in rats [152]. However, the observation that dosing felbamate monocarbamate to glutathione depleted rats failed to produce hepatotoxicity still indicates the existence of a potential confounding explanation for the species difference in toxicity. Regardless, mercapturate conjugates of felbamate-related material have been observed in human urine and their structures were consistent with 2-phenylpropenal formation representing a significant metabolic pathway [153,154]. Indeed, the cyclic carbamate was suggested

Figure 5.6 Felbamate bioactivation.

to represent a latent precursor of 2-phenylpropenal capable of travelling to sites distal from the liver to cause, for example, blood dyscrasias [153,155]. Since the proposed bioactivation of felbamate is non-CYP450 mediated, and its metabolic turnover in human hepatocytes is minimal, Dcb values in the Pfizer protocols were <0.1 mg/day in both liver microsome and hepatocyte preparations. The conclusion from this work that felbamate is a nonhepatotoxin, therefore, represents a false negative outcome.

CBZ (Carbatrol, daily dose up to 1200 mg, Fig. 5.1) is probably better known for mediating severe adverse reactions of the hemopoietic system (aplastic anemia and agranulocytosis) and skin (Stevens-Johnson syndrome (SJS) and TEN [131]). CBZ bioactivation is believed to be CYP450 mediated with potential for this to occur in both the liver and skin [50]. Similarly, DHP (Phenytek, diphenylhydantoin (DPH), daily dose up to 600 mg) provides severe adverse events of the hemopoietic system, some of which have been fatal, and are believed to be related to its bioactivation by CYP450, prostaglandin synthetase, and myeloperoxidase enzymes leading to products that covalently bind to proteins capable of eliciting a hypersensitivity response [156]. Unlike felbamate, which elicits minimal toxicity in preclinical species, CBZ and DHP are known hepatotoxins in rat at high doses. CBZ and DHP provided robust levels of covalent binding in rat and liver microsomes (225–730 pmol drug equivalents/mg protein) in protocols used by Janssen, albeit at high concentrations *in vitro* (~300 μM) [157], but to lesser extents by other investigators where significantly lower concentrations were used [108,110,111]. CBZ and DHP are both capable of undergoing epoxidation (CBZ $\rightarrow$ CBZ-10,11-epoxide [51] and CBZ-2,3-epoxide; DPH $\rightarrow$ 4'-OH-DPH [156]) to form products that can either bind covalently to cellular macromolecules or drive oxidative stress via, for example, catechol-semiquinone cycling. Furthermore, bioactivation of 3-OH-CBZ and 4'-OH-DPH to free radicals by peroxidases (myeloperoxidase representing the major oxidative enzyme in neutrophils) will form reactive

oxygen species as a by-product and hence may represent an additional mechanism by which these drugs cause idiosyncratic drug reactions [158]. Covalent binding for CBZ and DHP in human hepatocytes is consistently lower than observed in liver microsomes and in the absence of an important role for metabolic conjugation reactions, one is led to speculate that these compounds, for example, may simply not enter the hepatocytes efficiently *in vitro* or that neutrophil activation should be weighted highly. Regardless, a prospective assessment of both CBZ and DPH in these protocols could quite reasonably result in a false negative categorization of these compounds.

These prior examples highlight both the fallible nature of predictive toxicology and the need to collect data from multiple sources with the aim of conducting the best integrated safety assessment possible. Such an approach is not founded only on a formulaic assessment of covalent binding and exposure to reactive intermediates (false negatives included sudoxicam and felbamate, a false positive was propranolol) but also on data emerging from a variety of technologies that provide ancillary information that collectively provide a qualitative evidence-based approach to risk management. Clearly, if one is able to eradicate metabolic activation during lead drug design, then the need to predict hepatotoxicity as a consequence of bioactivation is not relevant and the focus then shifts to assessments of other mechanisms of toxicity.

5.2.4 Deficiencies of Covalent Binding Studies

On the basis of the foregoing sections, a number of deficiencies can be highlighted with the conduct and interpretation of covalent binding studies and data, respectively, and include the following.

1. If a drug is extensively but slowly metabolized, standard incubation conditions may underestimate the potential generation of a reactive intermediate *in vitro*. Attention to incubation time and extent of metabolic turnover are therefore important [65,85], and are accounted for by approaches that integrate hepatic intrinsic clearance [108] and/or metabolic turnover [66].
2. Compounds that undergo non-CYP450-mediated bioactivation (e.g., by esterases) will not be “flagged” by assays that utilize liver microsomes. Similarly, drugs bioactivated in tissues other than the liver will not be detected in standard covalent binding assays that are based solely on the use of liver preparations.
3. Covalent binding studies performed with radiolabeled compound are often performed with and without the addition of chemical trapping agents in order to determine if binding can be attenuated. For MBIs of CYP450, the efficiency of this process can be very poor, presumably due to such highly reactive intermediates binding to constitutive amino acid residues in the active site of the CYP450 enzyme. At worst, the reactive intermediates formed can potentially escape the trapping process, thus interfering with the elucidation of the chemical mechanism of bioactivation or, at best, the efficiency of chemical trapping is significantly reduced, which markedly hampers the structure assignment of the trapped reactive intermediate [65]. Clearly, however, the finding that a candidate drug is an MBI highlights bioactivation has occurred. An example of this phenomenon is the MBI of CYP3A4 by mifepristone (RU486) where the stoichiometry of irreversible modification of the apoprotein at the active site was determined to be 1 mol of mifepristone bound per 1 mol CYP3A4 inactivated [159].

4. Some GSH adducts are not stable and are subject to chemical degradation/rearrangement or enzymatic degradation, thereby escaping conventional detection [160]. In certain cases, *N*-acetyl cysteine (NAC) can be used in place of GSH as a nucleophilic trap, although this agent may be less efficient than GSH if the conjugation reaction in question is catalyzed (even in part) by glutathione-*S*-transferase enzymes.
5. Glutathione-*S*-transferase activity may not be optimal in, for example, liver microsomal preparations and may need supplementing to support those conjugation reactions that are enzyme catalyzed.
6. Hepatocytes contain the full complement of metabolic enzymes (e.g., phase 1 and phase 2 enzymes), which addresses a common concern of using only a “CYP450-rich” liver microsomes experimental system for those research groups wishing to conduct a quantitative hepatotoxicity risk assessment. Since a significant perturbation of genes encoding for antioxidant enzymes, drug biotransformation enzymes, and drug uptake/efflux transporters occurs following hepatocyte isolation, it is important to control for this when selecting reagents to deploy toward covalent binding assays [161] by, for instance, appropriately characterizing such reagents and using a common pool of reagents deployed across multiple experiments (also applicable to liver microsomes).
7. During the conduct of covalent binding studies, a question of whether the nonrecoverable radioactivity is covalently bound or simply not extracted using the washing solvent system employed is sometimes encountered. This can be addressed using standard gel electrophoresis protocols and determining whether radioactivity comigrates with protein [159]. This approach may shed light on a discussion of relative toxicity following adduction of a few relative to multiple proteins. Integrating data on factors such as the magnitude of binding, the relative rate of binding, and the spectrum of proteins bound by reactive electrophiles is relatively under-researched. The La assay published by researchers at Abbott Laboratories allows for the detection of reactive molecules by NMR spectroscopy, where they concluded that slowly reacting compounds may be more likely to cause adverse events [162]. This is consistent with investigations into the role of arylation in quinone toxicity where cytotoxicity was governed by the rate of adduct formation *in vitro*; that is, paradoxically, higher chemical reactivity equated with lower cytotoxicity [163]. It is tempting to conclude that reactive intermediates that are slowly reacting are more capable of leaving the active site and perturbing a broader array of cellular proteins. This equates with a “more shots on goal” hypothesis of covalent-binding-mediated toxicity, which clearly needs to be balanced with factors such as whether the proteins adducted are “critical” for cell function in addition to the extent/amount to which exposure has occurred to the reactive intermediate and the downstream adducted proteins.

5.3 BIOMARKERS OF DRUG-INDUCED LIVER INJURY

In addition to having chemistry-based strategies to minimize potential for bioactivation, there is a clear need to understand the biochemical cascade of host cell defense and

repair in order to define robust biomarkers of DILI that are amenable for routine analysis—this forms the basis of the integrated “evidence-based approach” to risk management. Such assays bridge the intent behind rational structure-based drug design, which is “safety” for the purpose of this discussion, with a functional correlate that can be monitored preclinically and have relevance clinically; essentially addressing the deficit that currently exists for hepatotoxicity [5].

Measuring serum alanine aminotransferase (ALT) represents a widely used biomarker approach to detecting hepatocellular injury, yet it is neither specific to the liver nor do fairly high elevations always indicate or predict serious DILI and hence the degree of risk to the patient [164]. Watkins *et al.* have highlighted the limitations of ALT measurements using the example of tacrine where 25% of patients developed ALT greater than three times to that of upper limit of normal (ULN) with no associated cases of symptomatic liver injury or jaundice yet for troglitazone, a withdrawn drug, <2% patients developed ALT greater than three times to that of ULN. Satisfying Zimmerman’s (Hy’s) [165,166] rule (serum ALT >3X ULN and serum total bilirubin levels >2X ULN) as a criterion for discontinuing drug therapy is not tenable since the etiology of total bilirubin level increases resides with a major and often irreversible loss of functioning hepatocytes.

Toxicogenomics has some merit in highlighting hepatotoxicity risk but has struggled to realize its full potential since it represents a qualitative tool, data from which is difficult to translate to a risk assessment. McMillian *et al.* were able to select a 69-gene set to maximally separate compounds in control, macrophage activator, peroxisome proliferator, and oxidative stress/reactive metabolite classes of compound in rodents *in vivo* [157,167,168]. A key goal of this research was to detect as many classes of toxicant as possible before their pathologies were manifest and before gene changes becoming secondary to the pathology; essentially identifying gene expression changes that predict damage and are not as a result of cell damage. The Nrf-2 (nuclear factor-erythroid 2-related factor 2) regulated genes that were identified in rat liver, which were upregulated by oxidative stressors or reactive intermediates included NAD(P)H: menadiene oxidoreductase, microsomal epoxide hydrolase, glutathione-S-transferase, heat-shock protein 90, and γ -glutamylcysteine synthetase [168]. Roth *et al.* have also deployed microarray analysis on rat livers following prior modest induction of inflammation using lipopolysaccharide (LPS). This research has suggested a role for pro-inflammatory cytokines and neutrophils in trovafloxacin-induced liver injury [169]. This work complements findings from research conducted with cytokine knockout animals using APAP as the model hepatotoxin where, for example, anti-inflammatory IL-10 protects against toxicity (IL-10 null mice have increased susceptibility to APAP toxicity), whereas the pro-inflammatory IFN γ (interferon), FasL (Fas ligand), and TNF (tumor necrosis factor) promote an injurious outcome [170,171]. However, the role of animal models to study drug-induced hypersensitivity reactions overall has been limited [172]. Making these research efforts more relevant to humans is clearly the goal and the opportunity now exists to investigate this *in vitro* in human hepatoma cell lines [173]. In this regard, Takakusa *et al.* have investigated the induction profiles of Nrf2-related genes in human hepatocytes using the prototypic idiosyncratic hepatotoxicants, ticlopidine [174], diclofenac [175,176], clozapine [177,178], and tienilic acid [179,180] and concluded that induction of heme oxygenase-1 mRNA (HO-1; catalyzes the degradation of heme resulting in the production of biliverdin that can suppress oxidative stress by scavenging reactive oxygen species (ROS) [181]) is correlated

with the occurrence of reactive metabolite-mediated drug toxicity. This conclusion was supported by the finding that HO-1 induction could be significantly attenuated by the pan-CYP450 inhibitor, aminobenzotriazole [182].

High content screening (HCS) enables kinetic monitoring *in vitro* of live cells in real time for multiple cellular biomarkers using epifluorescence microscopy and image analysis [58,183]. Xu *et al.* [184] have conducted HCS in human hepatocyte cultures and measured mitochondrial damage, oxidative stress, and intracellular GSH as markers of mitochondrial energy and cellular redox states, since these have all been implicated as important predictors of DILI [185,186]. In isolation, this testing strategy had a positive rate of 50–60% when applied to >300 drugs including many that cause DILI, and a very low false positive rate of $\leq 5\%$. Of note, while there was not a big overlap between the compounds investigated by the two Pfizer groups ([108] vs [184]), the cellular imaging approach did correctly classify buspirone, paroxetine, propranolol, and raloxifene as non-DILI positive (this was not always the case when using only covalent binding protocols, see above), suggesting HCS to represent an important member of the preclinical repertoire of safety assays.

To reiterate, mitochondrial energy and cellular redox states have all been implicated as important predictors of DILI [185,186]. Mitochondria are a major source of ROS where superoxide anion radicals, produced as a by-product during respiratory reactions, are scavenged by superoxide dismutase (SOD) producing hydrogen peroxide and molecular oxygen. Boelsterli and Hsiao and Lee *et al.* have shown that hepatotoxicity consistent with necrosis was observed following troglitazone administration to *Sod2*^{+/-} mice, but not in control animals [187–189]. These heterozygous mice contain ~50% of the SOD activity compared to wild type animals, but activities are normal for catalase and glutathione peroxidase, and it was proposed that troglitazone-mediated toxicity was a consequence of increased levels of ROS in the livers of *Sod2*^{+/-} mice [190]. Similar investigations have been conducted with flutamide [191] and nimesulide [192] indicating that the *Sod2*^{+/-} mouse is a sensitive model to assess mitochondrial toxins and complements the HCS model already discussed.

Continuing on the general theme of impaired mitochondrial function, hepatic microsteatosis is considered to be caused by inhibition of fatty acid β -oxidation, which results in lipid accumulation. Metabonomic approaches have been used to indicate that APAP can disrupt fatty acid β -oxidation in wild-type versus *Cyp2e1*-null mice using a mass spectrometric approach to investigate the serum metabolome from these animals [193]. Similarly, ¹H-NMR of urine and liver samples has also been leveraged as a metabonomic approach to identify impaired fatty acid metabolism as the mechanism of DILI in rats [194], highlighting the usefulness of metabonomics in general to investigate toxicity mechanisms.

In the context of reactive metabolite-mediated toxicity, the discovery of Keap1 (kelch-like ECH-associated protein 1) as an endogenous “sensor” of chemical/oxidative stress is probably one of the most important discoveries of recent times; it also represents an example of a drug–protein interaction, which mediates detoxification. Human Keap1 contains 27 cysteine residues in its 624 amino acid structure and plays a pivotal role as a cytosolic repressor protein that binds the transcription factor Nrf2 and keeps it in the cytoplasm and targets it for proteosomal degradation. Upon challenge, which includes an electrophilic insult and/or GSH depletion, Nrf2 is released for nuclear translocation and binding to the antioxidant response element (ARE) [195]. In a competing transcriptional regulatory mechanism, Bach1 (BTB and CNC homology 1, basic

leucine zipper transcription factor 1) heterodimer binds to the ARE and represses defensive gene expression in what has been described as a competitive interplay between Bach1-containing repressor dimers and Nrf2-containing activator dimers [196]. The binding of Nrf-2 containing activator dimer to the ARE activates transcription of a myriad of gene products, which catalyse direct inactivation of oxidants (e.g., catalase and superoxide dismutase) and detoxification of electrophiles (e.g., glutathione S-transferase, epoxide hydrolase, and quinone reductase 1(NQO1)) as part of the “host defense” response [197]. In elegant studies performed in murine models by researchers at the University of Liverpool, UK, the ability of the Keap1-Nrf2 pathway to “sense” and respond to electrophilic metabolites/oxidative stressors appears to be via mechanisms other than direct modification of Keap1. This group demonstrated that Nrf2 can be activated by molecules that do not deplete GSH but do modify Keap1, by molecules that deplete GSH to <15% of basal levels and modify Keap1 and, thirdly, by depletion of GSH only [198]. Of note, these researchers were able to demonstrate that *N*-acetyl-*p*-benzoquinoneimine (NAPQI, the reactive metabolite of acetaminophen) selectively modifies Keap1 residues *in vitro* and that activation of the Nrf2-ARE pathway at non-toxic doses of acetaminophen occurs indicating that this pathway can “sense” and respond to chemical stress before the onset of cytotoxicity [198,199]. These are the first studies to elaborate how the processes of drug bioactivation, reactive metabolite formation, GSH depletion (Nrf2 activation), and reactive metabolite binding to cellular machinery (Keap1), can all integrally be involved in evoking a cell defense response. Similar findings have been reported for the *ortho*-quinone products of estrogen catechol metabolites which have been shown to activate Nrf2 via covalent binding to Keap1 [200].

In summary, while there are a battery of assays currently deployed in the current “reactive metabolite mitigation arsenal”, to include covalent binding assays (in hepatocytes corrected for daily dose and metabolic turnover), functional assays such as MBI and genotoxicity, and additional assays that evaluate BSEP inhibition and mitochondrial toxicity, there continues to be a diligent focus on supplementing this further. The foregoing discussions on the roles of liver function tests, toxicogenomics (+/– LPS), HO-induction, HCS, animal models (IL-10 null mice, *Sod2*^{+/-} mice, CYP450-specific knock-out animals), metabolomics and Nrf2 activation, ushers in the next logical question of whether there are additional screening platforms or early indicator biomarkers of liver toxicity that are available or emerging that highlight when cell defense mechanisms are becoming overwhelmed, but precede the onset of massive hepatocellular injury or a hypersensitive response, and include the following.

1. A Nrf2 luciferase-reporter assay has recently been developed in human HepG2 cells, which is amenable to high throughput screening [201].
2. Hepatic depletion of glutathione can be monitored by measuring increases in ophthalmic acid (L-γ-glutamyl-L-α-aminobutyryl-glycine; an analog of glutathione in which the cysteine moiety is replaced by L-α-aminobutyrate [202]) levels in plasma and hence has the potential to represent a relatively noninvasive probe to assess the redox status of the liver GSH system in humans [203].
3. HMGB1 (high mobility group box protein 1) is a chromatin component and has been shown to be released in a *hypo*-acetylated form from *necrotic or damaged* cells [204]. HMGB1 is ubiquitous at 10⁶ molecules per typical mammalian

cell, which is not, however, released from *apoptotic* cells. This finding is consistent with apoptosis not representing a present and immediate danger and, as such, there is no commensurate need to trigger an inflammatory response [205]. HMGB1 is also released in a *hyper*-acetylated form from activated immune cells and, therefore, may have use in identifying patients at risk of developing hepatotoxicity before the onset of overt injury [12,204]. Consistent with this finding, *Hmgb1*^{-/-} necrotic cells have a greatly reduced ability to promote inflammation [204]. Of note, in the context of experiments conducted by Roth *et al.* (see above), macrophages and monocytes secrete HMGB1 as a delayed response to activation by LPS [206]. HMGB1 also has been proposed as a “danger signal” (see above) to trigger an idiosyncratic toxicity [36,207].

4. Heat shock protein-72 (Hsp72) has also been proposed to be an endogenous “danger signal” and, like HMGB1, is released from necrotic cells but, unlike HMGB1, is also released by cellular stress [36]. Hsp72 stimulates production of proinflammatory cytokines by monocytes and macrophages [208,209] and surface-bound Hsp72 can be chemotactic for NK cells to induce cytolytic activity [210]. HMGB1 and Hsp72 detection is rudimentary currently and is typically based on Western blot analysis [211].
5. CK18 (cytokeratin-18) is widely expressed in epithelial and endothelial cells and has been proposed as a serum biomarker of necrotic (full length CK18) or apoptotic (caspase cleaved CK18) cell death [12]. Analysis of CK18 is performed by ELISA [212].
6. The disadvantages of ALT, as a specific serum biomarker of liver function, were discussed previously. MicroRNAs (mir) are small, noncoding RNAs that are relatively stable in plasma and have merit as diagnostically sensitive and specific markers of tissue injury [213]. Specifically, mir-122 and mir-192 are enriched in liver tissue and exhibit dose- and exposure duration-dependent changes in the plasma that parallel serum aminotransferase levels and the histopathology of liver degeneration following APAP administration to mice, but their changes can be detected significantly earlier. These findings suggest the potential of using specific circulating mir’s as sensitive and informative biomarkers for DILI [213,214]. Moreover, the sequence of miR122 is conserved from mammalian species back to, for example, zebra fish, rat, dog, and monkey, making findings in early pre-clinical studies potentially more translatable to humans [215].
7. The concept that patients are genetically predisposed to various toxicities is clearly enticing; the supposition being that patients “at risk” of developing a drug-related toxicity could be proactively screened in advance and potentially redirected to a safer drug therapy option. There exists highly significant association between single nucleotide polymorphisms (SNPs) in the MHC with skin and liver toxicity [216] as exemplified for skin toxicity induced by abacavir [217] and CBZ [218,219], and hepatotoxicity induced by amoxicillin-clavulanate [220], ximelagatran (Exanta) [44], ticlopidine [221], and flucloxacillin [222] (Table 5.6). If DILI genes all turn out to be in the HLA (human leukocyte antigen) region, it would be one of the strongest rationale for why animal testing offers no predictive value for most DILI in humans [223]. For many of these examples, the statistical significance of this genetic association is high when performed retrospectively. That is, when blood samples are taken from affected patients and

TABLE 5.6 HLA Genetic Markers of Liver and Skin Toxicity

Drugs	Allele or Haplotype	Comments
Abacavir	HLA-B*5701	Patients of this genotype can avoid abacavir and be prevented from developing toxic epidermal necrolysis (TEN) or Stevens-Johnson Syndrome (SJS)
Flucloxacillin	HLA-B*5701	For suspected cases of flucloxacillin induced liver injury, an estimated 85% of these patients would carry this allele
Carbamazepine	HLA-B*1502	This allele is strongly associated with carbamazepine-induced SJS and TEN in Han Chinese, but not in Caucasian populations
Amoxicillin-clavulanate	DRB1*1501- DRB5*0101- DQB1*0602	Study performed in white native patients originating from Belgium. This haplotype was present in ~12% of the normal control which is considerably higher than the 1/1000–1/10,000 incidence of hepatitis observed for this drug. HLA association cannot therefore be the only factor responsible to explain the pathogenesis of this disease
Ximelagatran	DRB1*07- DQA1*02	Ximelagatran does not undergo metabolic bioactivation, and it is therefore conjectured that this drug forms a low affinity association with MHC. DRB1 alleles have a carrier frequency of 11% in Scandinavia and 0.3% in Japan
Ticlopidine	HLA-A*3303	Ticlopidine-induced hepatotoxicity has an increased rate in Japanese compared with Caucasian patients and is strongly associated with this allele, which has a frequency of 9.7% in Japanese and 0.53% in Caucasians

analyzed *post-hoc* to determine if there is evidence of a genetic predisposition, the correlation is high. However, when the observation that many patients who do not develop an adverse reaction also carry this genetic association is coupled to the fact that the frequency of idiosyncratic drug reactions are low, the outcome is that using HLA association cannot typically be used prospectively to identify patients at risk of developing such reactions due to the high false positive rate of such an analysis.

8. The LTT does not fall into the category of a biomarker assay that can preempt the onset of drug hypersensitivity reaction, but is highlighted here as an assay

that has utility in understanding particular immune mechanisms in different drug allergy diseases, and has been reviewed elsewhere [40,224].

5.4 CONCLUDING REMARKS

Attenuating metabolic activation during drug design and defining biomarkers that are symptomatic of host cell defense machinery perturbation can collectively contribute to bringing safer and much needed drugs to the market for the long term benefit of patients. The body is clearly adept at handling electrophilic species resulting from drug bioactivation, and thiol chemistry (GSH, Keap1) is central to this cascade defense mechanism. Instances where this defense is overcome highlight the need to target compounds with as low a dose as possible, with minimal potential to form reactive metabolites, as one strategy to mitigate against potential toxicities. Utrecht [30] has reported that drugs given at a daily dose of 10 mg or less are rarely, if ever, associated with a significant degree of idiosyncratic drug reactions. In those instances, where compounds are progressed into clinical development despite their known ability to covalently modify endogenous macromolecules, a range of methodologies have been described in this chapter, which help to provide an evidence-based approach to an integrated safety assessment. A proposed specific goal for such programs would be to bring forward back-up compounds where further attenuation/eradication of metabolic activation has successfully been achieved while maintaining all other favorable properties of the compound. This investment is necessary to avoid those very late stage clinical development or postmarketing discussions with clinical investigators and regulators where liver toxicity and/or hypersensitivity adverse event data arise and sponsor company project teams are left with the benefit of hindsight wishing that a more proactive stance had been taken to overcome metabolic activation at the outset in the discovery phase, at least as one potential causative event in the toxicity outcome. This is especially relevant at a time when drug differentiation based on safety is so crucial to product success.

It should be emphasized that there is no straightforward or one standardized approach to the evaluation of the safety of drug metabolites. A case-by-case approach should be exercised when the information in the guidance does not apply.

—Aisar Atrakchi, *Chem. Res. Toxicol.*, 2009, 22, 1217–1220

6.1 INTRODUCTION

The Safety Testing of Drug Metabolites Guidance, also known as the *Metabolites in Safety Testing* or *MIST Guidance*, was issued by the FDA Center for Drug Evaluation and Research (CDER) in February 2008. This new guidance defined thresholds for

metabolite exposure in humans and preclinical species that would assure regulators that the preclinical species employed to define the safety of a drug candidate were in fact exposed adequately to all quantitatively significant human metabolites [1]. The US guidance was followed in June 2009 with the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) M3(2) guidance, which differed in important ways with respect to metabolite exposure thresholds, but sought to achieve the same result. Both guidances acknowledged the complexity of the issue and advocated for “case-by-case” strategies that are developed with Agency consultation [2].

Since July 2009, the pharmaceutical industry focus has shifted from the thresholds and logic of MIST, to practical implementation of bioanalytical aspects of plasma metabolite analysis. For example, a “holistic” strategy for practical implementation of MIST compliance was described [3], bioanalysts have started to address best practices [4], and reviews on the evolution of scientific thinking about MIST are now appearing [5–7]. Collectively, these efforts recently culminated in a special issue of *Bioanalysis* in July 2010 [8]. The number of MIST-related articles has grown from 17 in July of 2009 [7], to approximately 30 in Sept of 2010. Therefore, it is timely to look at what drug metabolism practitioners are likely to do to address MIST, against a plethora of possible approaches that mix some old and standard activities, such as *in vitro* cross species comparisons, with new approaches focused on plasma metabolite analysis.

This chapter outlines the elements of the roll out of a strategy to address the MIST guidances at Amgen. Our objectives were twofold: first, to highlight a strategy for implementing a MIST plan in Translational Sciences [an organization within research and development (R&D) divisions of some pharma and biotechnology companies that oversees activities approximately from the time a candidate is selected for advancement to first-in-human (FIH) through end of phase 2] and second, to illustrate the relative advantages of plasma pooling strategies and cross species semi-quantitative metabolite comparison by liquid chromatography–high resolution mass spectrometry (LC-HR-MS).

6.2 SCOPE OF THE CHAPTER

The history and pharmacokinetics and drug metabolism (PKDM) issues in the pharmaceutical industry’s implementation of the MIST guidance were reviewed up to July 2009 by Slatter and several others [4,6,7]. This chapter covers practical implementation and growing experience with the FDA and ICH guidances that occurred across the industry from the summer of 2009 to the end of 2010. Our experience with the development and implementation of a Translational-Sciences-wide MIST strategy will be illustrated with examples of a practical analytical strategy.

6.3 IMPACT OF MIST GUIDANCE ON INDUSTRIAL ADME RESEARCH

The 2008 CDER guidance flowchart is reproduced in Fig. 6.1 with an overlay that shows the numerous organizational codependencies that must be addressed in a MIST plan rollout [7]. The key effect of the MIST guidance was to shift most of the burden of

Contains nonbinding recommendations

compliance to absorption, distribution, metabolism, and excretion (ADME) practitioners. It was now PKDM's job to prove that any metabolite characterized would be "not disproportionate." In the less-than-likely event that a metabolite(s) was disproportionate, this had to be known early enough to alert drug safety and get metabolite synthesis, qualification, activity, and a safety testing strategy completed by the end of phase 2.

6.4 GUIDANCE HARMONIZATION BETWEEN THE FDA AND ICH

One key aspect of MIST compliance is the clarification in the past year of the quantitative threshold for metabolite scrutiny. The CDER threshold for a disproportionate metabolite was set in the guidance at 10 % of parent drug area under the plasma concentration–time curve (AUC) in human plasma at steady state. This threshold had the potential to increase the number of metabolites warranting scrutiny. ICH M3R2 defined the disproportionate metabolite threshold at 10 % of plasma drug-related material in drugs that were dosed at 10 mg or higher [2]. The latter threshold was more aligned with conventional ADME practice, as it was anchored to absolute dose mass, while the former threshold created a sliding scale relative to parent drug in circulation. As the relative AUC of circulating parent drug decreased relative to metabolites, more metabolites were above the 10 % of parent threshold [7,9,10]. Recently, FDA authors

Robison and Jacobs [11] clearly indicated, with the usual disclaimers, that when the CDER guidance threshold resulted in more metabolites warranting scrutiny than the ICH M3R2 guidance, threshold set by the latter could be used. This was scientifically rational and further enabled the industry to focus on metabolites that were quantitatively significant, relative to the mass of drug material administered.

The ICH S9 draft guidance “Draft Consensus Guideline Nonclinical Evaluation For Anticancer Pharmaceuticals S9” [12], like the CDER guidance, had an exemption for the evaluation of drug metabolites of cancer drugs. The ICH S9 guidance states “for disproportionate metabolites of anticancer agents, a separate general preclinical safety evaluation might not be warranted for patients with late stage or advanced cancer, as human safety of the metabolite would have been assessed in phase 1 clinical trials. If the parent compound is positive for embryofetal toxicity or genotoxicity then separate studies for the disproportionate metabolite might not be warranted. Unless there is a specific cause for concern, nonclinical testing of the metabolite is not warranted.”

6.5 A MIST STRATEGY

In the time following the availability of the CDER guidance in February 2008, content experts across the industry monitored the implementation of the guidance. At the PhRMA Drug Metabolism Technical Group’s (DMTG) Annual Roundtable with FDA in 2008, both the positive aspects and some of the shortcomings of the guidance were discussed. PKDM program representatives conducted individual candidate risk analysis and immediate course corrections for their current clinical programs. Over the ensuing year, as they monitored the rapid evolution of MIST guidance thinking in the public domain and tested key technologies internally, companies developed MIST plans by assessing and selecting best practices for metabolite analysis. The last step was soliciting input on the draft plan inside and outside the PKDM unit before a roll out to partner organizations (such as toxicology, clinical development, and regulatory).

6.5.1 Modifications of the ADME Development Plan

Several key departures from conventional ADME development were added to small molecule drug candidate development plans in order to enable the shift from an *in vitro* and excreta focused approach to a plasma focused plan. As shown in Fig. 6.2, pre-FIH activities, such as cross species metabolite profiling and metabolite identification in microsomes and hepatocytes, were performed to discern the second species that would have metabolism most similar to humans. Significant human metabolites in microsomes and differences in profiles between human microsomes and hepatocytes were used to predict the most likely human metabolites [13,14]. Overall, the predictive value of *in vitro* screening using human hepatic microsomes and hepatocytes is best for single oxidations and decreases for sequential metabolism and for phase II metabolites. *In vitro* metabolism data can be used to reassure stakeholders that PKDM’s efforts will generate a prognosis of “not disproportionate” in the majority of cases and provide lead time in those rare cases where more data are needed. The most common complication at this stage comes as a result of lead enhancement to reduce metabolism, and some leads with good pharmacokinetics (PK) are slowly or negligibly metabolized *in vitro*. Nonetheless, with a pending focus on plasma analysis, consultation with chemists and

Figure 6.2 Strategy: build a data-driven proactive MIST development plan for each small molecule candidate. Timescale and order of operations are approximate; to be adjusted based on program needs. pharmacologists on the feasibility of synthesis and activity testing of the most probable human metabolites begins after candidate selection for advancement to FIH.

The most significant departure from excreta-based development is the need to obtain plasma for metabolite analysis and compare metabolite profiles semi-quantitatively across species. The two preclinical options are a separate dose escalation PK study in the rodent and nonrodent species, or alternatively, to obtain unused plasma from toxicokinetic (TK) analysis in non-GLP or good laboratory practice (GLP) studies. The latter option has only recently become feasible due to the recent availability of sensitive and selective high resolution mass spectrometry (HR-MS) techniques. As such, retasking of unused TK and clinical study plasma was discussed with Drug Safety and Clinical opinion leaders. Factors in implementation were study timelines, maintaining GLP compliance, protocol revisions, sample archiving, metabolite stability, reporting results, and verification of the new HR-MS techniques (Section 6.9). New protocol/informed consent language and plasma sample handling processes for unused FIH single ascending dose (SAD) and multiple ascending dose (MAD) plasma were developed.

Agreement on the need for the new plasma metabolite analyses developed quickly, since the consequence of doing metabolism “the old way” could include a clinical hold at the end of phase 2. It was recognized that a proactive approach gained time for metabolite synthesis, qualification, and safety testing, in the unlikely event that a

disproportionate metabolite was observed. Initial plasma metabolite profiling focused on identifying human steady-state metabolites in MAD samples that exceed 10 % of drug-related materials (DRMs). If no metabolites were above this quantitative threshold, subsequent comparisons to preclinical species would become unnecessary. Proximity of metabolites to the 10 % threshold would determine how prudent it would be to rely on similar observations in the definitive human ^{14}C ADME study. According to the guidance, the human ^{14}C ADME study is still the definitive proof for human metabolite exposure, albeit from a design that is typically single dose. We anticipate that HR-MS will supplant the human ^{14}C study as the definitive determination of circulating human metabolites because most researchers in the industry are moving toward HR-MS techniques to profile nonradioactive metabolites earlier in clinical development. These techniques were not as well established when the guidance was developed. As such, case-by-case arguments to regulatory authorities for the absence of disproportionate metabolites will probably be advanced before the completion of the human ^{14}C ADME study. Suitable protocol language to enable these analyses was developed proactively for clinical and preclinical safety protocol templates.

The observation in MAD samples of human plasma metabolites that exceed the 10 % of DRM threshold would trigger the analysis of unused TK samples from preclinical safety studies, or samples from a separate PK dose-ranging study, conducted to address this issue.

PKDM development team representatives are now expected to provide an ongoing MIST guidance risk assessment to their management, educate their development team, and refine their development plans to allow time to react after pivotal MIST data from the human MAD study become available. When there are no unique human metabolites, or the human metabolites greater than 10 % of DRM are unambiguously “not disproportionate,” these data can be included in a dedicated metabolism report that integrates all the available metabolism data and makes a clear case that further metabolite monitoring or metabolite assessments are not needed. This final report can be submitted in the routine annual update to the common technical application (CTA). In the alternate scenario, a disproportionate metabolite triggers dialogue with drug safety, clinical, regulatory, and pharmaceutical sciences to address the issue in a case-by-case way. The actual *in vivo* testing of disproportionate metabolites is complicated, as the ADME of separately administered metabolites may not be equivalent to the ADME of the metabolite generated *in vivo* [15,16]. There are also concerns over the potential toxicological irrelevance of any study on a separately administered metabolite [17].

The main values of the phase 1 centric plasma analysis approach are the lead time garnered for dealing with either an unique or disproportionate metabolite(s) and the ability to defer the human ADME study to after clinical proof of concept, with minimal risk of a surprise.

6.6 NEW APPROACHES TO NONRADIOACTIVE METABOLITE QUANTITATION: FOCUS ON PLASMA SAMPLE POOLING, HIGH RESOLUTION MS, AND MASS DEFECT FILTER MASS SPECTROMETRY

6.6.1 Plasma Availability and Plasma Pooling Strategy

Preclinical TK and SAD/MAD PK plasma bioanalysis do not consume all the available sample. It is therefore possible to use unused plasma for exploratory metabolite

profiling and avoid dedicated preclinical PK studies or additional human subject cohorts. The plasma volumes that are typically unused from different PK and TK studies after routine parent drug are shown in Table 6.1. Plasma from no observed adverse effect level (NOAEL) doses in animals, or maximum feasible dose and the best estimate of the effective dose in human SAD/MAD studies (if this can be predicted by target coverage) are appropriate to show metabolite coverage across species.

A semi-quantitative estimate of all the drug-related components that contribute to the total DRM AUC is obtained from time-proportional pooling of left over plasma volumes from different time-points across the sample collection period. This method is referred to as the *Hamilton-pool* or the *AUC-pool* [18] and is well documented [19]. An example of the necessary pooled sample volumes for a hypothetical time course of sample collection is shown in Table 6.2. A plasma aliquot volume from each time-point is selected based on the interval between time-points and the pooled sample is created volumetrically or gravimetrically.

The AUC-pool approach has several advantages. The metabolite profile from an AUC-pool provides a valid semi-quantitative estimate of each metabolite's contribution to total drug-related exposure (AUC) or to a separately measured parent drug exposure, as required by the guidances. The approach requires only a single liquid chromatography–mass spectrometry (LC-MS) injection from a single pooled sample, rather than the separate analysis of individual points in the concentration versus time

TABLE 6.1 An Example of Unused Plasma Sample Volumes from PK and TK Analysis

Species and Study Type	n/Dose-group	# Time-points	Plasma Volume (μL)	Volume for Metabolite Profile (μL)/Animal
Rat PK	3	9–12	100–120	50
Dog/monkey PK	3	10–12	225	175
Rat 4-d TK	3	5	80	50
Rat 10-d to 6-mo TK	4–5	5–6	120–160	70
Dog/monkey 10-d to 6-mo TK	3–4	6	200–400	70
Human PK	>4	9–12	700–1000	500–900

The remaining volumes can be used for a relevant metabolite profiling, avoiding the expense, time, and additional animal usage involved in separate studies. Unused plasma can be pooled across time and/or across animals with no changes to current PK and TK sampling approaches. If dried blood spot analysis is required or becomes common, separate plasma samples from animals or subjects may be needed to enable metabolite analyses.

TABLE 6.2 The Time-Proportional Plasma Pool

Time (h)	0	1	2	4	8	24	Sum
Δt - pool (μL)	5	10	15	30	100	80	230

The “AUC-pool” measures metabolite contribution to total AUC. These principles are well established in the literature and enable the use of unused plasma from TK analysis to afford a reasonable estimate of exposure in one LC-HR-MS run. Pooling across animals/subjects further enables measurement of an “average” exposure to the full slate of plasma metabolites. The plasma volumes would be available from either a PK or TK study.

curve. The plasma volume requirements are well within the range of unused volumes from completed quantitative GLP analyses of parent drug (Table 6.1). The AUC-pool may be built for each individual animal or subject in the study or the plasma from different animals/subjects may be pooled to comprise a single average exposure estimate for all the individuals in the study. If plasma volumes are too limited or time-points are sparse, individual time-points could be analyzed or a separate study or sample cohort would be necessary.

6.6.2 High Resolution Mass Spectrometry (HR-MS) Methods

New HR-MS methods now provide a unique ability to discern all metabolites in biofluids with high resolution and sensitivity without dosing a radiolabeled drug. High resolution mass spectrometers with time-of-flight and Orbitrap [20] architectures have the analytical and data analysis capabilities to conduct HR-MS screening of plasma samples. These mass spectrometers allow an accurate determination of mass/charge ratio (m/z) of both the base mass spectrometry (MS) peak and its collision-induced dissociation (MS^n) fragments down to millimass or higher accuracy. After acquisition of LC-HR-MS data, techniques such as mass defect filtering, background subtraction, and isotope ratio filtering can discern both parent drug and drug-related metabolite peaks in the chromatogram.

The mass defect of a pseudomolecular ion is the difference between its high resolution m/z and its nominal m/z (e.g., if an analyte's high resolution m/z was 500.1234, its mass defect would be 0.1234 Da). Mass defects of a drug and its metabolites are similar, within predictable ranges, and importantly, are different from most endogenous interferences [21,22]. A suitable range above and below the mass defect is selected (e.g., ± 100 mmu) based on the parent drug accurate mass and logical biotransformations and ions are "mass defect filtered" to distinguish the drug and its metabolites from endogenous interference ions [23,24]. When control sample such as predose plasma is available, comparing its high resolution liquid chromatography–mass spectrometry (HR-LC-MS) profile with a dosed sample allows for every metabolite to be found based on the mass defect filter (MDF) alone without use of any biotransformation templates. Figure 6.3 illustrates the sensitivity and selectivity of the approach with plasma collected after a single dose of a [^{14}C]-labeled compound. The top and middle panels are an ultra performance liquid chromatography (UPLC) unfiltered total-ion chromatogram and corresponding MDF chromatogram, respectively. The bottom panel is the radiochromatogram obtained on a conventional high performance liquid chromatography (HPLC) with an in-line radiometric detector. The HR-MS-MDF profile recapitulates the radio-profile.

Background subtraction is another way to process the LC-HR-MS data. A difference chromatogram is obtained by subtracting the dosed plasma profile from a predose profile. Historically, this method has been sensitive to retention time shifts that can occur between the two LC runs. A new algorithm tolerant of retention time shift and that has additional noise filtering has been described recently [25]. Isotope ratio filtering can also be applied if the parent drug and metabolites have atoms with high abundance +2 isotope ions (e.g., Cl and S) [26].

Metabolite related information evolves throughout development and there is a sequential accumulation of both qualitative and quantitative data that eventually are integrated to discern any disproportionate metabolite. The plasma MDF data can be

Figure 6.3 Metabolite observation by LC-HR-MS-MDF profiling. TIC, total ion chromatogram. (See color insert.)

compared to human and preclinical *in vitro* metabolite profiles and to the available preclinical *in vivo* ^{14}C ADME data.

Unfortunately, MDF metabolite profiles are not quantitative, and due to a number of factors, the MS response of the parent drug and metabolites can be different. These include electrospray ionization differences, ionization quenching by co-eluting endogenous compounds, or differences in solvent gradient composition at different elution times. When synthetic standards are available, the MDF profile peaks can be semi-quantitatively compared to metabolite mass by calculating response factors. MS response can be compared with response factors calculated from the diode-array detector (DAD) response across a wavelength range [19], with a radiolabeled metabolite peak area [27,28], or based on NMR quantitation of an isolated metabolite [29]. Each type of MS response factor calculation has its own limitations [30,31]. MS ionization methods employing lower flow rates appear to mitigate the ionization differences and new methods such as captive-spray ionization are being developed [31,32].

The HR-MS-MDF approach described here uses parent drug concentrations that were separately determined by validated LC-MS methods to benchmark the MDF response of each metabolite. Benchmarking to parent drug concentration enables semi-quantitative comparison of every human metabolite to comparably benchmarked pre-clinical plasma data. This approach to the MDF metabolite profile is illustrated in Fig. 6.4. The top panel shows a hypothetical HR-MS-MDF profile from an AUC-pool of plasma obtained from preclinical safety species at steady state. The bottom panel shows a human circulating metabolite profile obtained from an AUC-pool of plasma collected following either a single or a multiple oral dose. A qualitative examination

Figure 6.4 Estimation of circulating human metabolite coverage by obtaining HR-MS-MDF profiles of AUC-pooled plasma from human and safety species; and compute and compare the relative “AUC_M” from each profile.

reveals whether the metabolites observed in human were also found in preclinical safety species for the program. For a given metabolite, relative coverage can be estimated from the same data set without determining its actual concentration. Because the profile was obtained from an AUC-pool, the relative AUC of metabolite (“AUC_M”) can be computed:

$$AUC_M = \frac{M_{\text{area}}}{P_{\text{area}}} \times AUC_P$$

$$\text{Exposure multiple} = \frac{AUC_{M_{\text{preclinical}}}}{AUC_{M_{\text{human}}}}$$

where M_{area} and P_{area} are the peak areas of the metabolite and parent from HR-MS-MDF profile and AUC_P is the parent AUC, a parameter estimated already available from prior analysis using a qualified or validated bioanalytical method. Exposure multiple is then computed for each metabolite using the equation shown above. Metabolite coverage is satisfied if exposure multiple is equal to or greater than unity. The principal advantage of this method is that there is no requirement for any metabolite reference standard (synthetic, radiolabeled, or isolated). Furthermore, any interspecies metabolite abundance comparisons are focused only on metabolites that are quantitatively above the 10 % of DRM threshold in humans.

An analogous approach of estimating exposure multiple by simply computing the ratio of metabolite area in preclinical versus human from their HR-MS profiles was published recently [33]. In contrast to the approach advocated here, these authors do not benchmark metabolite abundance to the parent AUC in their exposure multiple calculations. In another variation, Gao *et al.* [34] have proposed measurement of relative plasma exposures. After qualitative metabolite profiling of AUC-pooled plasma discerns useful metabolite multiple reaction monitoring (MRM) transitions, a ratio of each metabolite and parent drug to an internal standard is measured by MRM on a triple-quadrupole mass spectrometer. In both methods [34,33], the dosed plasma is

mixed with the undosed comparator plasma, for example, dosed human plasma would be mixed with equal volume of undosed preclinical safety species plasma (or vice versa) to account for any potential endogenous interference in peak intensity that may arise from the mass spectrometric analysis. The drawback of this approach is unknown sample stability because addition of the undosed plasma could potentially alter metabolite levels due to species differences in plasma borne enzyme activities (e.g., esterases and amidases).

For any human metabolite that is at or near the 10% of DRM threshold, the higher the AUC_M in the preclinical safety species relative to human, the greater the confidence that the preclinical safety species covered the human metabolite. If the animal to human AUC_M ratio is close to 1 or lower, a synthetic standard and qualified bioanalytical method for the metabolite in question will probably be applied to enable a decision of whether the metabolite is disproportionate. A decision tree has been published that determines when a more rigorous analytical determination of a potentially disproportionate metabolite is needed [34].

Best practices incorporating a tiered analytical validation approach to metabolite quantification has been proposed by the European Bioanalysis Forum [4] and others [30,31]. Semi-quantitative estimation of metabolites by the HR-MS-MDF methods described above represents a screening method that will discern obvious and borderline disproportionate metabolites, but these methods do not constitute either qualified or validated assays that would be needed for further investigation of borderline cases.

6.7 THE HUMAN ^{14}C ADME STUDY

According to the CDER guidance, the human ^{14}C ADME is still the definitive study for human metabolite exposure and the impact of the guidance on the timing of the human ADME study has been discussed by Anderson *et al.* [30]. However, the Guidance did not foresee the technological advance of HR-MS-based mass defect filtering, which enables the visualization and semi-quantitative measurement of a slate of metabolites with minimal interference from endogenous peaks. The case-by-case provisions in the guidance enable a data-based argument to maintain the status quo for timing the human ADME study after clinical proof of concept and to use HR-MS-MDF analysis of plasma to drive earlier decisions on potentially disproportionate metabolites. There are specific cost advantages here, given the unfortunately high probability of compound termination at or before clinical proof of concept. There is still value in the human ADME study for discerning the rate and routes of excretion of radioactive metabolites and the complete recovery of the DRM. The non-ambiguous, quantitative measurement of radioactive metabolites and parent drug in plasma after a single radioactive dose in half a dozen healthy volunteers or patients can be used to corroborate the risk-based decisions on human metabolites that were built on the human MAD plasma profiles and by cross species comparison. The advantage of using the human ADME study for MIST strategy validation rather than MIST strategy development is completely avoiding the inferred need for a steady-state answer from a type of study that under almost all circumstances should be run as a single dose.

6.8 ACCELERATOR MASS SPECTROMETRY (AMS)-BASED HUMAN ADME STUDIES

Most companies conduct the human ^{14}C ADME study using a conventional radiochemical (ca. $100\text{ }\mu\text{Ci}$) dose and apply a liquid scintillation counting (LSC)-based detection whenever sensitivity allows. In cases where circulating radiochemical concentrations are low, accelerator mass spectrometry (AMS) will be necessary to obtain the requisite quantitative plasma metabolite profile. Accelerator mass spectrometers are essentially ^{14}C atom counters that enable plasma drug or metabolite quantitation many orders of magnitude below the limit of detection of LSC-based measurement [35]. Plasma obtained from a conventional $100\text{ }\mu\text{Ci}$ dose of a potent drug that affords very few radiocounts in plasma can be analyzed by AMS to obtain quantitative metabolite profiles. Alternatively, clinical human ADME studies can be conducted using radiochemical doses in the hundred nanocurie range, without a prerequisite rodent whole-body autoradiography-based radiodosimetry or the need for good manufacturing practice (GMP) radioformulation [36].

One drawback of AMS for quantitative metabolite profiling is that identification of isolated radioactive HPLC peaks is done by retention time only, as graphitization destroys the sample and affords only the quantitative data on ^{14}C atom concentration. Second, the analysis must be outsourced by most companies and AMS can be expensive when metabolism is extensive. The AUC-pool strategy can be used to decrease the cost of metabolite profiling by AMS. AMS vendors are all versed in the implications of the MIST guidance and have a unique ability to generate quantitative plasma metabolite profiles at plasma concentrations of radioactivity that are not measurable by any other method.

AMS vendors have proposed that AMS-based clinical designs could accelerate the human ADME study into phase 1 to address MIST. With the availability of the HR-MS techniques discussed above, this may be unnecessary except under unusual circumstances that might include exploratory investigational new drug (eIND) approaches for lead selection [37]. In the eIND approach, human metabolite profiles could be obtained by AMS from select superior leads being advanced to a full CTA. As such, AMS approaches within the eIND approach may enable earlier human plasma metabolite quantitation in select programs.

6.9 IMPLEMENTATION

After the final MIST guidance issued in February 2008, at Amgen, we monitored and contributed to the discussions occurring throughout the industry [7,38]. Some aspects of the guidance elicited extensive discussion in the 17 MIST-related papers published in 2009. Many of these publications focused on different analytical approaches to metabolite assessment and also made data-driven comparisons of our ability to predict the structure and relative importance of human metabolites in plasma (reviewed in Ref. 7). Some literature and company database meta-analyses on the probability that a metabolite will be disproportionate were developed [9,39]. An opinion paper from a CDER representative reiterated the case-by-case aspects of guidance compliance [40]. By the end of 2009, PKDM groups were testing and implementing strategies to comply with the FDA guidance when the December 2009 ICH M3(R2) guidance

became effective. It set a different and less conservative threshold of 10 % of DRM and dose greater than 10 mg. In papers and seminars from 2010, the focus shifted to the role of bioanalysts in MIST strategy and the industry converged on MS-based approaches [31].

Our initial strategy within PKDM was to triage discovery and development of small molecule programs and work with PKDM scientists to identify programs at risk for disproportionate metabolites. Development plans of affected programs were then modified to address the MIST guidances and team PKDM scientists embarked on case-by-case development team education and data generation. Meanwhile extramural and intramural experience grew and consistent internal procedures were developed. Opinion leaders in drug safety, early clinical development, regulatory affairs, and pharmaceutical development previewed the PKDM MIST strategy and helped develop best practices for plasma procurement and metabolite profiling. Discussions with chemists and pharmaceutical development revolved mainly around responsibility for an earlier synthesis of the major *in vitro* human metabolites to enable activity testing and use as analytical standards. In some cases, depending on synthetic complexity, biogenesis of the metabolite(s) [41] may be required and purification and determination of analytical purity can be done by NMR [29] or a variety of MS techniques [31].

Good laboratory practice/good clinical practice (GLP/GCP) compliance and metabolite stability aspects of procuring unused plasma from preclinical safety and human SAD/MAD studies were worked out. The use of unused plasma and sample pooling is efficient and avoids the time involved in conducting separate studies. When clinical plasma becomes available, unused plasma could be obtained from GLP studies by amendment or from a separate PK study. Owing to uncertainties regarding metabolite stability, protracted cold storage of plasma for metabolite analysis is less desirable than the use of more recently procured samples. Non-GLP analysis of the plasma samples was preferred, with a bioanalytical report as the deliverable. After conducting the initial human plasma screening of the SAD and MAD samples, steady-state human metabolites at or near the 10 % of DRM threshold would be the reason for, and focus of, subsequent analysis of preclinical plasma samples.

Similar discussions with clinical development centered on mechanisms for the transfer of samples after PK analysis, suitable protocol, and informed consent language.

As in the analysis of preclinical safety samples, non-GLP analysis would be pursued and a bioanalytical report would be generated. Ultimately, a MIST summary report encompassing all the *in vitro* and *in vivo* metabolism data would be assembled along with a recommendation for any necessary subsequent activities. With adequate preclinical coverage, the recommendation would be no further metabolite profiling is necessary until the human ADME study. The report could be submitted in late phase 1, coincident with the next annual report to the CTA. Regulatory endorsement that all MIST issues are resolved would be requested. Clearly disproportionate metabolites or metabolites at or near the threshold would entail more interactive discussions on the path forward with teammates and regulators.

The responsibilities of the PKDM project leader were as follows: Develop a MIST action plan for their candidate, include a MIST risk analysis statement and related activities in monthly highlights, and engage development team partners. PKDM project leaders were to leverage available pre-IND samples for preliminary method development and analysis, arrange synthesis of key metabolite(s), and arrange determination of their pharmacological on target activity, with a team dialogue on how much activity data

were appropriate. Protocols were to be checked for appropriate sample retention, storage, and transfer. The PKDM project leader would discern human metabolites greater than 10 % of DRM first, compare other species as necessary, and then write MIST bioanalytical reports to compile into the consensus metabolism report and action plan. Recommendations might include subsequent metabolite(s) monitoring in TK studies and/or in larger clinical studies. When this is necessary, bioanalysts could be engaged in GLP method development, and regulatory and early development partners would then help define the more complicated, case-by-case path forward by discussion with regulators.

The rollout was conducted at unit meetings in preclinical safety and regulatory and clinical safety units. All the planning and rollout of these activities took about one year from initial discussions to endorsement and routine application. The plan evolved significantly over time as many new publications became available that discerned how the industry as a whole would deal with MIST guidance compliance.

6.10 CONCLUSION

This chapter overviewed the development and rollout of a plan to comply with new regulatory guidances on metabolites. A proactive, data-driven, best-practice approach was developed by consensus with key development partners. Changes to traditional metabolism approaches included nonradiometric profiling of plasma metabolites across species and the development of a data-driven plan to preclude the existence of disproportionate metabolites. When potentially disproportionate metabolites are observed, under this plan, there is still time to conduct subsequent metabolite assessments, well in advance of the end of phase 2.

Suddenly a mist fell from my eyes and I knew the way I had to take.

—Edvard Grieg, Composer (b1843–d1907) [42]

ACKNOWLEDGMENTS

We acknowledge valuable discussions with scientists in the Drug Metabolism Technical Group (formerly the PhRMA DMTG) and Amgen. We acknowledge with thanks the critical review of the manuscript by Drs. Bradley Wong, Larry Wienkers, Benny Amore, and Dean Hickman.

7.1 SUMMARY

This chapter focuses on the role of metabolites in determining drug efficacy and toxicity. Most drugs are administered orally, and therefore, the organs with the most immediate impact on their biological fate are the intestine, where absorption occurs, and the liver, where metabolism, elimination into bile, and movement into general circulation occurs. The primary enzymes responsible for phase I metabolism of drugs and

chemicals belong to the cytochrome P450 (CYP) family of proteins. Although these important enzymes are found throughout the body, they are in highest concentration in the liver. In recent years, the presence of CYP enzymes in the intestinal enterocytes and their effect on drug bioavailability, efficacy, toxicity and differences between species have been recognized.

This chapter presents the important role of intestinal and hepatic metabolism in determining the amount of parent drug and metabolites that can enter general circulation. Phase I metabolism can yield nontoxic (more) water-soluble products that can be subsequently conjugated to glucuronic acid, sulfate, or glutathione (GSH) by phase II enzymes. Phase I metabolism can also generate highly reactive (electrophilic) intermediates that are capable of covalently binding to and altering the function of essential cellular proteins, which can lead to cytotoxicity. The relative abundance and distribution of CYP enzymes and transporters in the intestine and liver are important determinants of these effects. Several examples of drug metabolism and bioactivation in the intestine and liver will be presented.

An essential component of any drug discovery program is to understand the potential adverse effects associated with new drug candidates. Initially, laboratories focused on the parent compound, but it is now clear that metabolic stability and bioactivation in the intestine and liver can have a significant impact on the safety and efficacy of new drugs. Extensive presystemic metabolism can reduce bioavailability, and production of reactive metabolites can increase the risk of toxicity. Many new compounds can be enzymatically converted to reactive intermediates capable of binding to, and altering the function of, essential cellular proteins or DNA. *In vitro* methods for characterizing metabolism, bioactivation, and cytotoxicity are presented. Emphasis has been placed on the relationship between the *in vitro* concentration that causes adverse effects and the expected *in vivo* maximum therapeutic plasma concentration. This provides a logical means of using *in vitro* models to identify potential hazards while at the same time linking these effects to an *in vivo* parameter. Finally, a road map for the collection and incorporation of *in vitro* data into a risk assessment and decision-making process, will be provided.

7.2 INTRODUCTION

The development of new drugs requires 12–15 years of research and nearly \$1 billion. One reason for the high cost is the high percentage of promising new drug candidates that are dropped because of unanticipated adverse effects in either preclinical or clinical safety trials. Over the past 10 years, there has been a significant change in the standard process of drug discovery and development. The incorporation of *in silico* and *in vitro* test systems into the hit-to-lead and lead optimization phases of drug development has significantly reduced the attrition rate. The key to the successful utilization of *in vitro* data to predict adverse outcomes in animals and humans is incorporating a disciplined *in vitro* testing strategy that includes multiple endpoints, tissue-specific models, multiple exposures, and a method for including the data obtained into the decision-making process. Nearly all pharmaceutical companies now include some form of an early toxicity screening process into their discovery process; however, many of these groups are not consistent in how they use the information obtained. A failure to understand the biology of the cell model being used as the test system, the use of limited endpoints

for toxicity, and exposure concentrations that are far above those expected *in vivo* under therapeutic conditions have made it difficult to consistently extrapolate the *in vitro* data to *in vivo* effects. Relating the *in vitro* exposure concentration to the actual plasma concentrations during repeated dosing in animals and humans is an essential component of predictive *in vitro* screening. In order to accurately use *in vivo* plasma concentration as an anchor for *in vitro* studies, it is important to understand how a new chemical entity (NCE) is metabolized. The enzymes involved, the metabolites formed, and the role of presystemic metabolism provide important insights that enable more accurate predictions of *in vivo* events from *in vitro* data. Knowledge of drug metabolism is a critical component to the development and evaluation of new drug candidates. Although the information from *in vitro* models for absorption, distribution, metabolism, and elimination (ADME) is typically acquired, the information is often left out of *in vitro* toxicity screening approaches where the goal is to identify liabilities and predict the probability of an adverse event not only in animals but also in humans. The inclusion of *in vitro* kinetic data greatly improves the models' predictive power. The purpose of this chapter is to provide an understanding of why and how *in vitro* endpoints designed to define metabolic stability, presystemic metabolism, and the formation of reactive metabolites can improve the process of hazard identification and risk assessment. Although drug metabolism can occur throughout the body, this chapter focuses on intestinal and hepatic metabolism, as the intestine and liver are the primary sites of absorption, metabolism, and presystemic transformation of orally administered drugs.

7.3 PHASE I AND PHASE II METABOLISM IN THE GASTROINTESTINAL TRACT

The oral route is one of the most common means of administering medicine. Efficacy and toxicity are determined by the corresponding concentration of the drug in plasma and tissues. The fraction of the dose absorbed across the intestine into portal circulation and the fraction that passes through the liver into systemic circulation determine the bioavailability of the drug. Bioavailability is determined by three distinct phases. The first phase is the fraction of drug that leaves the intestinal lumen (F_a) and does not degrade in the lumen or end up excreted in feces. The second phase defines the amount of drug that survives metabolism within the intestinal cells (F_g). The third phase is the fraction of the parent drug that leaves the liver without metabolic transformation (F_h) [1]. Loss of drug in the lumen (F_f) and metabolism in the liver (F_h) have long been considered to have the most significant impact on bioavailability (F). It is now clear that intestinal phase I and phase II metabolism of drugs also have a significant impact on the systemic exposure of orally administered drugs.

Metabolism of drugs in the intestinal enterocytes by phase I and phase II enzymes and active transport out of cells by P-glycoprotein (Pgp) are important in determining oral bioavailability [2]. Although several CYPs have been identified in human intestine (CYP1A1, CYP2C8–10, CYP2D6, CYP2E1, CYP3A4, and CYP3A5), by far, the most abundant and most important with respect to drug absorption is CYP3A4. This enzyme represents only 30–40% of the total hepatic CYP pool but 70–80% of the intestinal CYP pool and has activity that is equal to or greater than that found in the liver [2–5] (Fig. 7.1). Determining the portion of the administered oral dose that reaches general

Figure 7.1 Comparison of the relative abundance of CYP proteins in human liver and intestine.

circulation (%*F*) is important for determining an efficacious or therapeutic dose, tissue interactions, and toxicity. When orally administered drugs are rapidly metabolized before entering general circulation, they are said to undergo first-pass metabolism. Intestinal metabolism by phase I and phase II enzymes participates in biotransformation of absorbed drugs before reaching the liver. In the liver, the parent drug (as well as primary metabolites) is subject to additional (secondary) metabolism. As a result, orally administered drugs that are substrates for CYP enzymes can undergo substantial metabolic transformation before ever reaching systemic circulation. Although intestinal metabolism of drugs has been known to occur, it was generally believed that the liver played the primary role in first-pass metabolism. This belief changed when it was discovered that CYP3A4 existed not only in the liver but also in the intestinal mucosa [4]. Cyclosporine and midazolam are rapidly metabolized by gut CYP3A4 before reaching the liver and therefore the gut plays an important part in first-pass metabolism. Midazolam metabolites (1-hydroxy and 4-hydroxy) can then be conjugated with glucuronic acid by UDP-glucuronosyltransferases 1A4, 2B4, and 2B7 (Fig. 7.2) [6]. Because CYP3A4 is known to metabolize and detoxify more than half of the prescribed drugs, its presence in both the intestine and liver cannot be overlooked.

The anticancer drug docetaxel (Taxotere) provides an excellent example of the significant role that intestinal CYP3A4 can have on drug efficacy and toxicity. This drug

Figure 7.2 Midazolam metabolic pathways.

is used to treat advanced breast cancer. Like most cytotoxic antitumor drugs, docetaxel has a narrow therapeutic window and large interindividual variation in exposure and clearance. Therefore, any change in its absorption or elimination will have a significant impact on its efficacy and toxicity. The use of knockout mice that express CYP3A in liver, but not in their intestine, to study the uptake and metabolism of docetaxel revealed a dramatic increase in plasma levels reflected by an increase in $C_{\max}$, $\%F$, and AUC_{oral} relative to wild-type mice that have both intestinal and hepatic CYP3A4. When the situation was reversed, mice that lacked hepatic CYP3A, but expressed intestinal CYP3A, had much less total absorption into the general circulation, with significant reductions in $\%F$, Cl , and AUC_{oral} . It was concluded that the presence of CYP3A in the intestine had a greater impact on the amount of drug entering general circulation than CYP3A metabolism by liver alone. However, the hepatic expression of CYP3A was most important in determining the clearance of drug [7]. Clinically, docetaxel is given as a 1-h intravenous drip. This route of administration bypasses gut metabolism and relies on liver metabolism for clearance (Fig. 7.3).

The sleep aid triazolam was also evaluated in a mouse CYP3A knockout model. Triazolam is a classical substrate for CYP3A, but not for the export pump Pgp [8]. In knockout mice that lacked all CYP3A, the metabolism of triazolam was significantly reduced. Like docetaxel described above, intestinal metabolism by CYP3A played an important role in controlling drug exposure. When the CYP3A inhibitor ketoconazole was coadministered with triazolam, there was a substantial increase in triazolam exposure, which was due to the inhibition of CYP3A4 metabolism. If CYP3A expression

Figure 7.3 Metabolism of docetaxel.

was induced by the administration of a drug such as gefitinib, the level of systemic exposure was lower due to increased metabolism [8]. These findings are important because they demonstrate the barrier role that intestinal metabolism can play. This type of drug–drug interaction (DDI), when one drug induces the metabolism of another, is termed *heterotropic positive cooperativity*. Knowing how coadministered drugs affect CYP induction and inhibition is important for predicting adverse events [8–10].

Warfarin has been used extensively to prevent thromboembolic complications associated with atrial fibrillation. Because this drug has a narrow margin of safety, serious DDIs can occur when administered with drugs that inhibit its clearance. In humans, CYP3A4 is the primary enzyme responsible for warfarin metabolism, which produces the 3-hydroxy and *N*-oxide metabolites. Inhibition of CYP3A4 by fluconazole and

miconazole caused elevated plasma concentrations of warfarin and enhanced anticoagulation effects. If the drug was administered with compounds that induce drug-metabolizing enzymes, warfarin metabolism increases and plasma concentrations can decrease below therapeutic levels, resulting in a diminished (efficacy) anticoagulant effect [9].

Rifabutin is a broad-spectrum antibiotic used to treat infections in AIDS patients. The oral bioavailability of the drug is low and extremely variable ranging from 3% to 42% [11]. When drugs known to be potent inhibitors of CYP3A (e.g., fluconazole, ketoconazole, and clarithromycin) were coadministered with rifabutin in humans, both the peak plasma concentration and the AUC were substantially increased. The inhibition of CYP3A activity by ketoconazole or fluconazole in microsomes prepared from both intestinal enterocytes and liver showed that enzyme inhibition in the microsomes from the enterocytes was similar to inhibition observed in microsomes prepared from liver [12]. Interestingly, while CYP3A4 represents only 30% of the total human hepatic P450 content, it represents more than 70% of the CYP content in human enterocytes. This example as well as those already presented, indicate that the metabolism of orally administered drugs by intestinal CYP3A4 represents an important barrier to absorption.

A study in human patients undergoing liver transplant provides additional evidence supporting the importance of intestinal metabolism to bioavailability. In this example, cyclosporine was administered directly to the small intestine during the procedure. Subsequent analysis of portal blood showed that 25–50% of the parent drug had been metabolized [5]. A similar experiment was also done with midazolam, and the results showed that only 12% of the parent drug entered portal blood [2,13].

Clearly, the ability to separate intestinal metabolism from hepatic metabolism of a drug would be important in terms of predicting systemic availability. This separation was achieved in clinical pharmacokinetic studies by administering cyclosporine by i.v. and oral routes. The drug was given alone or in combination with a known inducer of CYP3A4 (rifampicin) or an inhibitor of CYP3A4 (ketoconazole). In this way, it was possible to separate the relative contributions of intestinal and hepatic metabolism to oral bioavailability [14,15]. Differentiation was based on the observation that the observed oral bioavailability (F) could be determined by taking the product of the fraction absorbed as parent drug by the intestine (F_a) and multiplying it by the fraction of parent drug that entered portal circulation (F_g), and by the unmetabolized portion of the drug that passes through the liver and into systemic circulation (F_{hep}) (Eq. 7.1) (Fig. 7.4) [16].

$$F = F_a \times F_g \times F_{\text{hep}} \quad (7.1)$$

The fraction that passes through the liver unmetabolized was determined by dividing i.v. drug clearance by hepatic blood flow. The results of experiments conducted in patients with cyclosporine revealed that cyclosporine bioavailability was controlled primarily by intestinal metabolism (F_g).

In clinical practice, there can be wide interindividual variation in the disposition or bioavailability of orally administered drugs that can be metabolized by CYP3A4. These changes can not only impact plasma concentrations and efficacy, but also influence compound toxicity.

As we have seen in the discussions thus far, the safety profile of a drug can be altered if its metabolism and clearance are inhibited, or induced because these effects

Figure 7.4 Diagrammatic representation of cyclosporine bioavailability.

can increase plasma concentrations above a safe level or decrease plasma concentrations below an efficacious level. Adverse events can also occur when a drug is metabolized to a reactive intermediate, which can bind to cellular nucleophiles (such as proteins) and alter their function. Orally administered drugs that undergo metabolic activation via CYP3A4 or other CYP enzymes can form reactive metabolites during absorption by the gut enterocytes and by CYP metabolism in the liver.

Nevirapine is a non-nucleoside HIV-1 reverse transcriptase inhibitor and was the first of its type to be approved by the US Food and Drug Administration (FDA) for combination therapy. This drug is widely used throughout the world and represents one of the most prescribed antiretroviral drugs in the developing countries. Despite its success, nevirapine has been associated with hepatotoxicity and skin rash. Although the exact mechanism(s) responsible for the observed toxicity has not been clearly defined, one possibility is the formation of reactive metabolites via CYP metabolism. It is known that this drug undergoes extensive metabolism in the liver, forming 2-, 3-, 8-, and 12-hydroxyl metabolites followed by phase II glucuronidation or sulfation. Formation of GSH adducts can be an indication of the formation of reactive metabolites. GSH adducts formed in human liver microsome experiments were found after metabolism by CYP3A4, 2D6, 2C19, and 2A6, with the greatest portion of reactive intermediate formed by CYP3A4 [17]. 12-Hydroxynevirapine has been associated with multiple DNA adducts [17–19] and with the formation of skin rash when dosed at concentrations lower than those of the parent drug. It is believed that reactive intermediates play a role in the liver toxicity of nevirapine and that metabolism to reactive intermediates can occur via two pathways (Fig. 7.5).

One pathway involves the formation of GSH adducts in the absence of phase II conjugation by a dehydrogenation mechanism to yield the quinone methide species.

Figure 7.5 Nevirapine metabolic pathways.

In vivo, the most likely pathway is sulfation, followed by spontaneous loss of sulfate and formation of the quinone methide, which binds to cellular nucleophiles. It is now known that sulfotransferases are present in the intestine. Therefore, the primary *in vivo* reaction described for nevirapine is likely to occur before the drug reaches the liver. This implies that high CYP3A4 activity in the intestine combined with the presence of intestinal sulfotransferases could increase the amount of 12-hydroxynevirapine and its sulfation product that reaches the liver. This combined with the fact that most patients receiving the drug are HIV positive, take multiple drugs, and have induced intestinal and hepatic CYPs or compromised liver health could explain at least in part interindividual differences in hepatic toxicity observed in this patient group.

Phase II conjugation enzymes which are responsible for glucuronidation and sulfation are present in the intestinal enterocytes [20–22]. These enzymes are now known to play a significant role in the bioavailability of drugs. For example, the bioavailability of orally administered salbutamol is quantitatively affected by the activity of sulfotransferase 1A3. Studies have shown that presystemic intestinal availability of salbutamol was lower than its presystemic hepatic availability [23]. These data provide evidence for a quantitative effect of sulfotransferases on the oral bioavailability of salbutamol.

When drugs have a high degree of cell permeability, the fraction lost in the intestinal lumen is low. An example is ethinylestradiol (EE), which has a $\log P$ of 4.52 and high cell permeability. As a result, nearly the entire amount of dosed drug enters the enterocytes, but <50% of the parent molecule remains after intestinal metabolism ($F_g = 0.479$). The fraction of the remaining parent drug then enters the liver where only a small fraction undergoes metabolism ($F_h = 0.874$) before reaching systemic circulation [1]. These data clearly indicate that for this drug, intestinal metabolism is the primary determinant of bioavailability. The presence of drug transporters, such as

Figure 7.6 Percentage of total CYP proteins in the human intestine.

MDR1, MRP, and OAT, can also have a significant impact on drug absorption. The reader is referred to a review by van de Kerkhof *et al.* [24] and others to begin learning about transporters in the intestine and their impact on drug absorption.

The presence of drug-metabolizing enzymes in the GI tract is highest in the more proximal regions. The duodenum and jejunum have higher activity than the ileum and colon, and this is true in both rats and humans. In humans, there are considerable interindividual differences in the relative abundance of each CYP isoform. This is due to polymorphisms, age, gender, diet, and the presence of medications. In general, CYP3A4 represents the greatest portion of the intestinal CYP protein (80%), followed by CYP2C9 (15%), CYP2C19 (2.9%), CYP2J2 (1.4%), and CYP2D6 (1.0%) (Fig. 7.6). Unlike the liver, CYP1A1/2 and CYP2D6 are either lacking or in very low abundance [24,25]. In general, the level of phase II conjugating enzymes present in the intestine decreases in the distal direction, although their abundance is not the same in all parts of the intestine. Sulfatase activity is high in the more proximal regions of the small intestine, but the highest activities have been reported in the colon. Glucuronidation activity for UGT2B1, 2B3, and 2B6 decreases in the distal direction; however, UGT1A1 and 1A6 activities are homogeneous throughout the small intestine. The colon possesses the highest activity of UGTs (UDP-glucuronosyl transferases) 1A1, 1A3, 1A6, and 1A8. Glutathione *S*-transferase (GST) activity has also been demonstrated in the intestine.

7.4 IN VITRO APPROACHES FOR DETERMINING THE ROLE OF INTESTINAL METABOLISM

Understanding the quantitative effects of intestinal and hepatic metabolism early in the drug discovery process is important for lead optimization and selection of a candidate molecule for preclinical safety studies. *In vitro* test systems that utilize subcellular fractions (e.g., microsomes), primary cells, whole-organ perfusion, and immortalized intestinal cell lines can be used (reviewed by van de Kerkhof *et al.* [24]). The Ussing chamber is primarily used to study permeability. The method involves the dissection of a small section of intestine, which is then placed into the chamber. An important

limitation of this system is that tissue viability is only for 2–4 h, making it difficult for use in toxicity studies. Primary intestinal epithelial cells can also be isolated; however, the yields are typically low and successful culture is difficult to optimize. Two other important *in vitro* methods for evaluating intestinal metabolism and drug toxicity are microsomes and precision cut intestinal slices (PCIS).

7.5 SUBCELLULAR FRACTIONS (MICROSOMES)

An excellent example that demonstrates the importance of characterizing intestinal and hepatic metabolic pathways before making predictions about clinical risk is illustrated in the work reported by Dalvie *et al.* [22] for the drug raloxifene (Evista). Raloxifene is an estrogen receptor modulator and is used therapeutically to treat osteoporosis and breast cancer. Raloxifene undergoes first-pass metabolism with an oral bioavailability of only 2%. *In vitro* systems have demonstrated the formation of a reactive metabolite and the subsequent formation of GSH and protein adducts. Bioactivation occurred in both human and rat liver microsome experiments (Fig. 7.7).

Interestingly, despite the *in vitro* data, no significant drug-related adverse events have been observed in humans who received the drug by oral administration. This apparent disconnect between the *in vitro* data and *in vivo* reality can be explained by understanding presystemic metabolism in the intestine and liver.

The *in vitro* experiment designed by Dalvie *et al.* [22] involved an initial incubation of raloxifene with human intestinal microsomes (HIM) and rat intestinal microsomes (RIM). This was followed by another incubation in either human liver microsomes (HLM) or rat liver microsomes (RLM) (Fig. 7.8). The data generated from this experiment clearly showed that intestinal phase I and phase II metabolism greatly reduced the amount of raloxifene that reached the liver. As a result, the intrahepatic concentrations of reactive metabolites were below those that would cause an adverse event.

The use of both intestinal and hepatic microsomal metabolism data can greatly improve the interpretation of the *in vitro* data. It is important to remember that microsomal systems do not possess the capacity to measure phase II conjugation metabolism. Therefore, either these enzymes and cofactors must be added or a more complete subcellular fraction, such as an S9 fraction, should be included. The primary advantages of using subcellular fractions are that they can provide information on the metabolic stability, metabolic activation, and relative metabolism of the intestine and liver both rapidly and at low cost. The information obtained can be used to identify drug inhibition, DDI issues, and species differences.

7.6 PRECISION CUT TISSUE SLICES FROM THE INTESTINE

Simple *in vitro* methods that enable the study of drug metabolism and toxicity in the intestine are limited when compared to those for other organs such as the liver. The intestine is highly heterogeneous with structural and functional differences between the duodenum, jejunum, ileum, and colon. PCIS provides a power tool for studying the impact of these regions on drug metabolism, bioavailability, and toxicity. Nonsolid tissue, such as from the intestine, can be prepared for tissue slicing by cutting a section of the intestine from the region of interest, ligating one end, and then filling it

Figure 7.7 Metabolic pathway of raloxifene.

with agarose maintained at 37°C. The agarose-filled section is allowed to solidify by cooling in an ice-cold medium. The section filled with agarose is then placed into the embedding unit and covered with low melt agarose to form a solid cylindrical organ base. Tissue embedding can be done using the tissue embedding unit from Alabama R&D (Munford, AL) [26]. The embedded tissue can then be sliced using either a Krumdieck *et al.* [27] or Brendel-Vitron [28] slicer (Fig. 7.9).

Studies comparing the quality of slices prepared from each slicer showed no appreciable differences [29]. The Krumdieck slicer is fully automated and can be set to a continuous mode. The Brendel-Vitron slicer is manual but has the ability to oxygenate tissues, which the Krumdieck slicer does not have. The use of these slicers enables the preparation of reproducible tissue slices with uniform thickness. For intestinal tissue, the slices are typically between 150 and 400 µm in thickness. A standard culture medium consists of Williams medium E with glutaMAX supplemented with antibiotics.

Figure 7.8 Sequential exposure of drug to rat and human intestinal and liver microsomes. UDPGA, UDP glucuronic acid.

Additional supplements have been suggested as a means of improving viability and extending culture time, including insulin, hydrocortisone, methionine, and fetal calf serum [30,31].

PCIS possess good viability for up to 24 h and have both phase I and phase II metabolizing enzymes. The viability of rat and human PCIS has been well studied and shown to have good morphology, to maintain constant ATP levels, and to provide a steady metabolic rate for both phase I and phase II enzymes for at least 3 h [26,32–33].

Precision cut tissue slices (PCTS) have several advantages over primary cell culture, cell lines, and subcellular fractions. They maintain tissue architecture and the relative abundance of different cell populations typically found *in vivo* and possess both phase I and phase II enzymes. Many slices can be prepared from a single animal, thus extending the endpoints that can be monitored in a single experiment. Finally, the method allows for slices to be prepared from other organs in the same animals (e.g., liver and intestine) and from multiple species. For a detailed review of PCTS and a well-described protocol, see the article by de Graaf *et al.* [30].

7.7 HEPATIC METABOLISM AND TOXICITY

The liver controls many key functions *in vivo*, which include maintaining plasma glucose levels, energy storage, fat metabolism, uptake and secretion of lipoproteins, cholesterol synthesis, bile formation, and the metabolism and elimination of exogenous

Figure 7.9 (a–l) Diagrammatic representation of precision cut intestinal slices. (See color insert.)

chemicals. The liver is situated anatomically in a unique position to control the systemic exposure of drugs and chemicals absorbed from the intestine. As such, it effectively separates presystemic from systemic circulation. The liver is the primary site for drug metabolism, a process that in most instances reduces drug toxicity, increases solubility, and speeds elimination from the body. However, as already discussed in this chapter, there are many examples where phase I metabolism can produce a highly reactive metabolite that can covalently modify essential cellular proteins, resulting in toxicity. Therefore, it is generally recognized as a good practice to determine whether NCEs can be metabolized to reactive intermediates.

P450 enzymes are ubiquitous proteins with highest concentrations in the liver. The five major classes of CYP enzymes involved with drug metabolism in humans are CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4 [34]. These enzymes carry out phase I reactions that can lead to the formation of innocuous metabolites and elimination of the drug or they may result in the formation of reactive metabolites that may cause adverse effects. Reactive intermediates can alter normal cellular function by covalently binding to macromolecules, such as DNA/RNA, proteins, and lipids. Many drugs can be metabolized by more than one CYP enzyme. It is important to know not only that a reactive metabolite is formed, but also which CYP enzymes are responsible. The identification of a reactive intermediate is not the only determinant of *in vivo* toxicity. It is also important to identify the enzyme pathway involved and its prominence in the tissue where an adverse event is detected. This will determine the

levels of metabolite that can be achieved in the target tissues. It is also important to know how a patient's age, gender, current health, and drug regimen may increase the toxic potency of the metabolite. This knowledge can then be used to assess the risk of an adverse event in humans.

Acetaminophen (paracetamol or APAP) is generally considered to be a safe drug. It is used to reduce pain and fever. It has no anti-inflammatory properties and thus is not a member of the class of drugs known as *nonsteroidal anti-inflammatory drugs* (NSAIDs). Brodie and Axelrod (1948) were the first to suggest that APAP can be used for medicinal purposes, and in 1955, APAP went on sale in the United States under the brand name Tylenol. APAP can cause liver toxicity when taken at doses higher than those used clinically in normal individuals. Toxicity has also been observed in alcoholic individuals who take prescribed therapeutic doses. APAP can be directly conjugated with glucuronic acid by UGT or with sulfate by sulfotransferases, which inactivate the drug and enhance its excretion into urine. A small amount of APAP is metabolized by CYP enzymes to a reactive intermediate *N*-acetyl-*p*-benzoquinone imine (NAPQI) (Fig. 7.10). At normal therapeutic doses, NAPQI can be detoxified by conjugation with GSH. At high doses or when CYP enzymes are induced by other medications or alcohol, the percentage of NAPQI can increase thus leading to a reduction in GSH levels. This in turn allows NAPQI to covalently bind to proteins causing liver toxicity [35]. The reduction in GSH levels in the liver triggers the activation of the Nrf2/Keap1/ARE signaling pathway, which induces the expression of cytoprotective proteins. APAP metabolism can deplete cellular GSH levels, and activation of this pathway increases the expression of proteins responsible for GSH synthesis, such as γ -glutamylcysteine synthetase [35].

Identifying whether a new drug can undergo metabolic conversion to reactive intermediates is important for understanding the risk of human toxicity. The reactive intermediate is the hazard, but the risk of human liver toxicity is determined by having the ability to predict the dose that will result in over production of the undesired metabolite which can cause a depletion of the natural defense mechanisms. Factors such as age, gender, disease status, the use of other drugs, degree of covalent protein binding, specific proteins targeted, and high alcohol usage can predispose individuals to APAP toxicity [36,37]. The balance between metabolic activation of a drug and the liver's ability to detoxify determines whether tissue toxicity will occur. The primary defense of the liver against the reactive electrophilic compounds is the tripeptide GSH. GSH is present in high (millimolar) concentrations in the liver and is the first line of defense against electrophilic molecules. If the concentration of reactive metabolites exceeds the capacity of the liver to detoxify, then toxicity may ensue. Reactive intermediates may also damage mitochondrial function, which could result in the generation of reactive oxygen species (ROS), leading to oxidative stress and lipid peroxidation. Oxidative stress can induce the Nrf2/Keap1/ARE signaling pathway, which regulates the expression of several protective proteins [38,39] (Fig. 7.11).

An important lesson learned through understanding the mechanisms of APAP-mediated liver toxicity is that the presence of the reactive intermediate alone is not the sole determinant of tissue toxicity. The cellular concentration of the metabolite is important, but other cytotoxic mechanisms induced by the initiating event can also dramatically increase the risk for tissue damage. It is now known that hepatocytes, Kupffer cells, and endothelial cells all participate in APAP-induced liver toxicity [36]. The formation of NAPQI at high levels reduces GSH levels, which leads to covalent

Figure 7.10 Acetaminophen metabolic pathways.

protein binding, disruption of mitochondrial function, and generation of ROS produced by each of the cell types mentioned. The result is the formation of peroxynitrite radical and superoxide anion. High levels of the peroxynitrite radical lead to protein nitrosylation, while high levels of superoxide lead to lipid peroxidation (Fig. 7.12). Both pathways result in liver toxicity.

7.8 *IN VITRO* DETERMINATION OF CYP INHIBITION AND POTENTIAL DRUG-DRUG INTERACTIONS

It is now generally recognized that the fraction of the dose metabolized by CYP enzymes is a major factor that determines the extent of drug interaction. When one drug

Figure 7.11 Nrf2/Keap1/ARE signaling pathway. IL-8, interleukin 8 AKR, aldoketoreductase; TXN, thioredoxin.

Figure 7.12 Mechanisms of acetaminophen toxicity.

inhibits the metabolism of another drug, there are changes in basic pharmacokinetic parameters that can reduce efficacy or increase toxicity and this is defined as a *DDI*. Terfenadine, bromfenac, alosetron, cerivastatin, and serzone are only a few examples of drugs that have been withdrawn from the market because of CYP-mediated DDIs [34]. A comprehensive list of clinical drugs reported to be mechanism-based CYP inhibitors can be found in the review by Zhou and Zhou [40]. It is important to understand which CYP enzymes are responsible for a drug's metabolism as well as the potential of a drug or its metabolites to induce or inhibit CYP enzymes.

Determining the CYP enzymes capable of metabolizing a drug is known as *cytochrome P450 reaction phenotyping*. For a comprehensive review, the reader is referred to the article by Zhang *et al.* [41]. Reversible or competitive inhibition of CYP enzymes is also an important component of early drug safety evaluations. The most important type of inhibition with respect to metabolites is time-dependent inhibition (TDI). TDI occurs when there is a change in drug potency during an *in vivo* exposure period. Some mechanisms underlying TDI are formation of inhibitory metabolites and mechanism-based inhibition (MBI). Three types of MBI have been reported: (i) the formation of inhibitory metabolites that inactivate CYP enzymes by covalently binding to the heme moiety, (ii) covalent binding to the apoprotein, and (iii) the formation of chelates or coordinates with the heme moiety [42]. This type of inhibition is clinically considered to be of far greater risk than competitive and reversible inhibition [40]. The greatest effects are seen under conditions of multiple dosing. Moreover, the formation of reactive metabolites may also predict TDI. Most mechanism-based irreversible inhibition is by definition due to the formation of a reactive metabolite that covalently binds to the CYP and inactivates it. Several *in vitro* methods have been described for identifying competitive inhibition and TDI [40,42].

7.9 *IN VITRO* DETECTION OF REACTIVE METABOLITE FORMATION

The incorporation of *in vitro* methods for the detection of reactive metabolites and oxidative stress early in the lead optimization phase of drug development provides important data that can be used to select the candidate with the highest probability of success in the preclinical safety studies.

Compounds undergoing metabolic activation may form soft or hard electrophiles. Soft electrophiles such as quinones, epoxides, quinone imines, and quinone methides can be trapped by GSH [43]. Hard electrophiles such as iminium species and aldehydes do not bind well to GSH but can be trapped using potassium cyanide (KCN) and the products detected by mass spectrometry or LC/MS/MS [44,45]. A rapid indirect method for determining bioactivation of new drug candidates is to monitor GSH depletion instead of GSH adducts. This is accomplished by preparing a standard reaction mixture containing potassium phosphate buffer (100 mM; pH 7.4), hepatic microsomes (0.5–1 mg/mL), NADPH (1 mM), test drug (10 μ M), and GSH (1 mM). The reaction is initiated by the addition of NADPH, and the incubation is allowed to continue for 30–60 min. The reaction is stopped with either an equal volume of ice-cold acetonitrile or 10% trichloroacetic acid added in a volume that is 15% of the total reaction volume. The samples are centrifuged at $10,000 \times g$ for 15 min at 4°C to precipitate protein, and the supernatant is processed for the detection of total GSH equivalents using the recycling method described by Tietz [46] and later modified by Griffith and

Figure 7.13 Correlation between covalent protein binding and GSH conjugate formation in rats and humans.

Meister [47]. Depletion of free GSH molecules is used as an indication of reactive metabolite formation and subsequent binding of GSH (Fig. 7.13) [48–50].

The formation of GSH conjugates has been shown to correlate with covalent protein binding *in vitro* and *in vivo* in both human and rat models (Fig. 7.13) [49]. When the data are expressed as a covalent binding rate in min/mg protein, it is possible to compare the relative binding between drugs in the same group. In Fig. 7.14, the toxicity profiles of three compounds are shown after exposure to rat hepatoma (H4IIE) cells. Buthionine sulfoximine (BSO) is a prototypical inhibitor of GSH synthesis, and the depletion of cellular GSH levels follows a concentration-dependent pattern. Azathioprine is a purine synthesis inhibitor that results in the loss of ATP. It is also known to disrupt mitochondrial function, leading to oxidative stress and depletion of GSH. Leflunomide treatment caused a significant loss in cellular GSH levels at low exposure concentrations. It is important to note that in each of these examples, cell viability remained high, as determined by membrane integrity (MemTox). Endpoints that indicate mitochondrial effects (3-(4,5-Dimethylthiazol-2-yl)-2,5 diphenyltetrazolium bromide (MTT) or ATP) and cell proliferation (Cell #) can be affected by exposure concentrations and times that do not cause cell death. MTT can be reduced intracellularly by reduction reactions in mitochondria, cytosol, endoplasmic reticulum, and lysosomes. Therefore, it is important to include other markers of energy production as indicators of mitochondria function. These could include ATP or mitochondrial membrane potential ($\Delta\Psi$). These endpoints are commonly used as markers for assessing cytotoxicity, yet the interpretation of effect is greatly influenced when more than one endpoint is used. This example illustrates the importance of using multiple endpoints in the *in vitro* model for correct interpretation of the data obtained [50].

Phenothiazines, such as thioridazine and chlorpromazine, were introduced in the 1950s as tranquilizers and antipsychotic drugs. Because of their antipsychotropic effects, these drugs are often administered together with antidepressants to treat many disorders including psychotic depression and depression associated with schizophrenia. Despite the clear benefits of these drugs, there have been reported cases of rare, but severe, hepatic injury [51,52]. The hepatic injury associated with these drugs was labeled idiosyncratic in nature. Recent studies have demonstrated that many of the idiosyncratic drug toxicities in liver can be traced to the formation of reactive metabolites [53–55]. Chlorpromazine and thioridazine undergo extensive “first-pass”

Figure 7.14 The importance of multiple endpoints for the interpretation of *in vitro* cytotoxicity data.

metabolism. The primary metabolites generated from phase I P450 enzymes are the products of hydroxylation, N-dealkylation, N-oxidation, and S-oxidation. The 7-hydroxy form of both the drugs can undergo additional oxidation to form an electrophilic quinone imine (Fig. 7.15).

The enzymes involved in the formation of the reactive intermediates are CYP2D6 and CYP1A2, with the former being more active than the latter. One possible explanation for the idiosyncratic nature of the liver toxicity associated with these drugs could be that CYP2D6 represents a small percentage of the total hepatic P450 enzymes under normal conditions. Therefore, in order for toxicity to occur, a larger amount of drug would need to enter the liver following absorption from the GI tract because CYP2D6 is in very low levels in the intestine. Metabolism in normal individuals by CYP3A4 in the intestine to nonreactive metabolites could greatly reduce the amount of parent drug that the liver would receive and hence reduce the formation of the reactive intermediate mediated by CYP2D6. In elderly patients, or patients on drugs that could inhibit CYP3A4 metabolism in both the intestine and the liver, the amount of drug reaching the liver would be greater. Thus, more drug would be shunted to secondary pathways that produce toxic metabolites, such as CYP1A2 and CYP2D6, leading to a higher tissue concentration of the toxic intermediates, which results in liver injury.

Figure 7.15 Bioactivation pathway for chlorpromazine and thioridazine.

GSH binding can serve as a surrogate for binding to more complex proteins. When the electrophilic intermediate formed is relatively stable, this method works well; however, some reactive products do not bind to GSH. This is true for amodiaquine, isoniazid, and valproic acid [56]. In addition, some metabolites lead to the generation of oxidative stress via an increase in ROS or nitrogen species, which would also not bind directly to GSH. Therefore, in addition to determining bioactivation potential, it is important to monitor the formation of ROS (superoxide anion and hydrogen peroxide), lipid peroxidation, and redox enzymes (GSH peroxidase, GSH reductase, catalase, and superoxide dismutase). Drug-induced changes in mitochondrial membrane potential ($\Delta\Psi$) can cause a release of superoxide anion and hydrogen peroxide into the cytosol. As a result, it is also important to monitor compound effects on mitochondrial membrane potential $\Delta\Psi$.

7.10 *IN VITRO* DETERMINATION OF COVALENT PROTEIN BINDING

The formation of highly reactive drug metabolites can cause cytotoxicity by the covalent binding of the metabolites to key cellular proteins and disrupting normal cell function. Adverse drug reactions are positively correlated with covalent protein binding. By quantifying the amount of protein binding that occurs following metabolic activation, it is possible to assess the risk of an adverse event *in vivo*. Clearly, the target proteins affected, as well as the site of binding, are important factors for developing a causal relationship between metabolic activation, protein binding, and cell or organ toxicity [57–59].

To determine covalent protein binding of a new drug candidate, radiolabeled drug is incubated in a standard reaction mixture containing potassium phosphate buffer (pH 7.4), EDTA, and MgCl_2 . Radiolabeled drug at a final concentration of $10\text{ }\mu\text{M}$ and specific activity of $10\text{ }\mu\text{Ci/mg}$ microsomal protein, and NADPH are added to

the mixture. The reaction mix is then incubated for 45 min at 37°C. The reaction is quenched by adding an equal volume of ice-cold acetonitrile, sonicating for 5 min, and then centrifuging at $20,800 \times g$ for 10 min. The supernatant is then removed and the protein pellet extracted with methanol–water (3:1 v/v) twice. The extracts are then combined with the supernatants and evaporated to dryness under an inert gas, such as nitrogen at room temperature. The dried residues are then solubilized in solvent for HPLC and quantified by LC/MS/MS [59]. A threshold value of 50 pmol drug equivalent per milligram protein has been proposed as a means of selecting drug candidates with the lowest activation liability.

Predicting *in vivo* adverse outcomes from *in vitro* data requires caution and a well-defined and disciplined approach for data collection and evaluation. For example, ethinyl estradiol (EE) is the active estrogenic component of birth control pills. EE has a high level of covalent protein binding *in vitro* (1200 pmol equivalents per milligram protein) but very low *in vivo* binding levels (<5 pmol). This is due to the fact that the primary routes of metabolism *in vivo* are phase II conjugation with sulfate and glucuronic acid. This, combined with low oral dose and high gut metabolism, significantly reduces the *in vivo* toxicity. This example underscores the importance of a detailed evaluation and elucidation of a new drug candidate's metabolic pathways in the presence of both phase I and phase II systems [58]. In addition, more accurate *in vitro* to *in vivo* extrapolations are possible when multiple methods are used to identify the hazard and assess risk. In the case of EE toxicity, a clear understanding of the relative contributions of phase I and phase II metabolic pathways, combined with metabolic stability experiments in microsomes from rat and human intestine and liver, would add the needed perspective for assessing the risk of *in vivo* toxicity. Moreover, this series of evaluations can be done using preparations from rat, dog, monkey, and human in order to gain an understanding of species-specific risk.

7.11 IN VITRO DETERMINATION OF OXIDATIVE STRESS

The accumulation of ROS can be measured using the fluorescent probe 5-(and-6)-carboxy-2',7'-dichlorofluorescein diacetate (CM-DCFDA) [60]. In this assay, nonfluorescent DCFDA readily crosses the cell membrane. Once in the cell, the acetate moiety is cleaved by endogenous esterases, which prevents leakage out of the cells and activates dichlorofluorescein (DCF) for binding to ROS (e.g., hydroperoxides and lipid peroxides which produces a fluorescence signal) [60–63]. The cleaved molecule cannot cross cell membranes and is therefore trapped inside the cell. The formation of ROS occurs rapidly, so it is important to conduct this experiment over shorter exposure periods (e.g., 1–4 h). The loading concentration of the DCFDA is typically 2–10 μM for 60 min, but this should be optimized every time the cell model is changed. An increase in fluorescence due to ROS binding is measured at an excitation wavelength of 503 nm and an emission wavelength of 529 nm. An example of data obtained from this assay in rat hepatoma (H4IIE) cells can be seen in Fig. 7.16. Two hydroperoxides, *t*-butyl hydroperoxide and cumene hydroperoxide, produced rapid increases in the DCF signal. Rotenone inhibits mitochondrial respiration, which leads to a release of superoxide anion. This process requires more time, which is detected by the assay as a delay in the increase in fluorescence. In comparison, a chemical like menadione

Figure 7.16 (a–c) Measuring intracellular reactive oxygen species with DCFDA.

(data not shown), which requires metabolism via CYP1A1/2 to the reactive quinone, required more time to increase the oxidative stress signal.

7.12 IN VITRO DETERMINATION OF MITOCHONDRIAL MEMBRANE PERMEABILITY

Mitochondrial damage can also cause an increase in ROS. This can occur when the membrane potential is disrupted, which allows superoxide anion to leak into cell cytosol. Therefore, it is also important to evaluate the effects of new drug candidates on mitochondrial membranes. A commonly used assay is based on the uptake of the fluorescent dye 5,5', 6,6'-tetrachloro-1,1', 3,3'-tetraethyl-benzimidazolylcarbocyanine iodide (JC-1). JC-1 is taken up by healthy mitochondria where it forms aggregates as the inner membrane becomes polarized. The ratio of the monomer to aggregate JC-1 is measured and used to determine changes in $\Delta\Psi$. The data are collected by using an excitation wavelength of 490 nm and then quantifying the monomer at 535 nm and the aggregate at 595 nm. The ratio of aggregate to monomer fluorescence determines the effect on mitochondrial membrane potential [60].

7.13 PRIMARY HEPATOCYTES IN SANDWICH CULTURE

All the endpoints discussed above can be measured in a single *in vitro* model. Primary hepatocytes in sandwich culture are considered to be the gold standard for determining drug metabolism and toxicity *in vitro*. The isolated hepatocytes are seeded onto culture plates that have been coated with a collagen matrix. After an attachment period, the cells are covered with another growth matrix, which can be either collagen or Matrigel. Cells cultured in this manner provide more sustained metabolic capacity and possess both phase I and phase II metabolism, which can be determined by monitoring disappearance of the parent drug and formation of metabolites. This model provides a means of measuring metabolic stability, reactive metabolite formation by measuring GSH conjugates and depletion of GSH, and oxidative stress using DCFDA.

Cell culture models should be used with multiple endpoints that measure cell health and a broad range of exposure concentrations. These include ATP levels, cell proliferation, reduction of MTT, and membrane integrity [50]. These parameters combined with the information described above will provide important information on a drug's potential for causing an adverse event *in vivo*. Hepatocytes from rat, dog, and human can provide insight into potential species differences and may guide the selection of the nonrodent species required in preclinical drug safety studies.

7.14 FUTURE *IN VITRO* MODELS FOR ASSESSING HEPATIC DRUG METABOLISM AND TOXICITY

Recent advances in cell culture technologies have allowed the introduction of 3D liver models. These models incorporate all the major hepatic cell types and can be sustained in culture for three to four weeks with stable metabolic capabilities. InSphero Inc. (Zurich) has introduced rat and human liver models in which hepatic spheroids

Figure 7.17 Diagram of the bioreactor designed by RealBio Inc.

containing all liver cell types, functional canalicular membranes, and good metabolic capacity can be used in 96-well format for early drug evaluations of efficacy and toxicity. Bioreactors, such as the model distributed by RealBio, Inc., Kalamazoo, MI, offer the potential to have not only extended culture times, and all major cell types present, but also the ability to control fluid/nutrient flow and oxygen content. In this system, isolated liver cells (a heterogeneous slurry) are perfused into the reactor. The cells settle onto and into the porous scaffolding and begin to aggregate and grow in a manner similar to that *in vivo*. This model is still under development for liver work, but preliminary data is promising (Fig. 7.17).

7.15 CONCLUSION

This chapter has focused on the role that metabolism and drug metabolites play in determining the safety of a new drug candidate. Emphasis has been placed on intestinal and hepatic metabolism and how drug metabolism in these organs contributes to first-pass metabolism, bioavailability, efficacy, and toxicity. *In vitro* approaches for obtaining many of the key parameters necessary for predicting *in vivo* effects were presented. It is important to realize that the use of multiple *in vitro* methods and endpoints provides more robust data sets. A careful evaluation of *in vitro* data that takes into consideration the intended therapeutic area of the drug, duration of exposure, maximum plasma concentrations for efficacy, patient population, age, gender, and health status will enable discovery scientists to make go-no-go decisions with confidence. When an intelligent and disciplined approach to the acquisition of *in vitro* data is incorporated into the drug discovery process, it is possible to select drug candidates that are not only efficacious but safe.

ACKNOWLEDGMENTS

I would like to thank the entire research team at CeeTox Inc. for providing some of the data examples presented here and for their hard work and dedication toward the development of *in vitro* methods to predict toxicity. To Dr. Philip Burton for critically reviewing the manuscript, to Ms. Muriel Reva for her extraordinary contributions to administrative preparation of the manuscript, and to my wife, Lindsay P. South, who gives me the space needed to write and who provides excellent editorial advice.

8.1 SUMMARY

The pharmaceutical industry is challenged by high rates of attrition during development because of preclinical and clinical toxicities that are not adequately predicted using current preclinical testing paradigms. In order to decrease late-stage attrition and improve success rates, it is necessary to consider on- and off-target-mediated toxicities at an earlier stage in product development in order to shift attrition upstream in the process. This should reduce resource-intensive developmental activities, such as preclinical toxicology and human clinical studies, on compounds that are ultimately destined to fail. Large-scale gene expression profiling technologies, such as toxicogenomics, are being applied preclinically during drug discovery and lead optimization to diagnose and predict drug-induced effects, including efficacy, toxicity, and pharmacokinetics. This includes the prediction of common hepatic effects, such as hepatic necrosis and hepatocarcinogenicity, and the mechanistic understanding of common drug-induced effects, such as hepatomegaly, cholestasis, and oxidative stress. The effect of nuclear receptor activation, particularly of pregnane X receptor (PXR) and the constitutive androstane receptor (CAR), can be studied by evaluating the gene expression response to nuclear receptor activation, both *in vitro* and *in vivo*. When used together with classical pharmacokinetic parameters, toxicogenomics can provide an understanding of the pathways (phases I and II) of drug metabolism induced by drug treatment. A more thorough understanding of drug safety and metabolism at an earlier stage of drug discovery and development can improve our ability to translate findings to higher species, including humans. Such information can also help define appropriate screening strategies to avoid offending toxicophores, or even to avoid targets that are associated with intolerable side effects at efficacious doses. Finally, applying gene expression

profiling to *in vitro* cell-based models may allow for the prediction of hepatic effects, such as phospholipidosis, and for hazard identification by evaluating pathways diagnostic of common mechanisms of toxicity. This chapter focuses on the application of toxicogenomics in drug discovery for the prediction and mechanistic understanding of drug-induced toxicity, as well as understanding mechanisms of drug metabolism for small-molecule therapeutics.

8.1.1 Introduction to Toxicogenomics

Toxicogenomics can be broadly defined as the application of large-scale gene expression profiling technologies for the prediction and mechanistic understanding of chemical-induced toxicity [1]. The practical applications of toxicogenomics are broad and include the safety assessment of drugs [2], environmental pollutants [3], industrial chemicals [4], nanotechnology [5], and natural products [6]. In addition to the safety assessment of drugs, it has also been applied to understand drug pharmacology and off-target pharmacodynamic effects that affect drug metabolism and drug–drug interactions [7,8].

The technologies available for measuring and statistically analyzing mRNA levels at a genome-wide level using microarrays and related to global gene expression have previously been well described [8–11], and the reader is encouraged to consult these reviews for more detailed technical information. There is also a plethora of public databases of chemical–biological interactions and gene and pathway annotation to facilitate the biological interpretation of gene expression changes [12]. This chapter focuses on the practical applications and interpretation of large-scale gene expression profiling for safety assessment in the field of drug discovery and development; encompassing both prediction and mechanistic assessment of common drug-induced toxicities. The utility of gene expression profiling to understand pharmacokinetics, drug–drug interactions, and other metabolism-mediated toxicity is also discussed.

8.1.2 Gene Expression Profiling Technologies

The oligonucleotide microarray platform [13] has emerged as one of the most common and widely available methods for measuring mRNA abundance in human cell and tissue samples. The availability of complete DNA sequences for many model organisms has also made whole genome expression profiling possible with oligonucleotide-based microarray platforms. This includes most animals commonly used for preclinical drug safety testing such as the mouse, rat, canine, and nonhuman primates. One of the major drawbacks of using microarrays for some preclinical species, particularly canines and nonhuman primates, is the relatively low level of sequence annotation in these model species compared to the human or rodent genome, which is more fully characterized. However, by virtue of comparative sequence analysis and identification of gene orthologs, the function of many poorly annotated genes can be hypothesized and potentially contribute to the understanding of gene function in model organisms [14].

More contemporary gene expression profiling technologies, the so-called next generation sequencing (NGS), have recently emerged and are based on high throughput sequencing of individual RNA molecules [15,16]. The ability to sequence individual RNAs and count the number of those sequences provides a higher resolution and possibly more accurate account of the transcriptome. It also has the advantage of detecting

and quantifying small noncoding RNAs (ncRNAs) [17] such as microRNAs (miRNAs), small interfering RNAs (siRNAs), and Piwi-interacting RNAs (piRNAs) that are not typically represented by oligonucleotide or complementary DNA (cDNA) microarrays, which have historically relied on gene-prediction algorithms for identifying protein-coding genes and their expressed sequences.

The advancement of NGS is rapidly changing the options available for quantitating RNA and is likely to revolutionize the way genomes are analyzed. The application of NGS to toxicological research, however, is only beginning as our understanding of the biological significance of ncRNAs is only just emerging. Numerous publications indicate that these small ncRNAs play an important role in regulating mRNA stability and function, thereby indirectly regulating protein expression and cellular functions relevant to cancer, metastasis, fibrosis, and development [18]. The miRNAs have also been reported to be a potential new source of biomarkers for diagnosing tumors [19] or for noninvasively detecting drug-induced toxicity as a result of their enhanced plasma stability relative to mRNA [20]. While exciting new efforts have emerged in this field, our understanding of the role of miRNA in regulating mechanisms of toxicity is in its infancy. Their putative role in a number of important diseases implies that they may become important players in our understanding of chemical-induced toxicity [21,22]. The field of toxicogenomics continues to evolve as do new technologies and analytical approaches; however, the majority of our understanding of predictive and mechanistic toxicology has come from cDNA and oligonucleotide microarrays combined with, or anchored to, phenotypes and pathways derived from traditional or more established molecular, biochemical, and pathological endpoints [23]. This evolution has positioned toxicogenomics as an established tool within drug discovery and development to advance our ability to predict toxicity and understand the mechanisms of drug action.

8.1.3 The Challenges of Drug Discovery and Development

A number of reports have attempted to calculate the cost of drug development and have reported a general decline in productivity based on the decreasing number of new chemical entities that have reached the market in recent years [24]. The cost of drug development has been hotly debated; however, based on one study, it has been estimated to cost approximately US\$800 million to US\$1.1 billion to develop a new drug [25]. The majority of these costs are associated with the expense on other development compounds that ultimately fail because of late-stage preclinical or clinical failure and the trial and error process of drug discovery. As a result, the effect of reducing late-stage attrition can considerably improve productivity and ultimately lower the cost of developing new drugs.

The low success rate and the failure of the pharmaceutical industry to improve productivity offered by advances in new technologies and our increased understanding of disease biology have provoked government and industry to reevaluate the process of drug discovery and development. Alternative means to improve productivity of the industry and expedite the pace of research to bring effective and safe therapies to market as efficiently as possible have ushered in new collaborative efforts across industry and government [26]. In response to these challenges, the pharmaceutical industry has concentrated on improving the critical aspects of drug discovery and

development that have historically contributed to late-stage attrition, namely, human and animal toxicity [27].

It is common for previously unidentified adverse effects in humans to be identified in later stages (phase II or III) of clinical development when tens of millions of dollars have already been invested. Detecting toxicity in earlier (phase I) clinical trials is challenging as a consequence of the limited number of healthy volunteers or patients enrolled in these early trials. The low sample size limits our ability to detect low incidence events such as liver toxicity. Statistically significant increases in the incidence of adverse events are often only identified after marketing approval when a larger number of patients have been observed. However, these postmarketing conditions are not well controlled as in a clinical trial and the adverse effects can be confounded by other factors such as disease state or other drugs.

Before human trials, the only other means of assessing human safety is to utilize animal toxicity studies, which are limited in their ability to detect toxicities that are relevant to humans. For instance, a retrospective evaluation of the concordance between animal and human toxicity indicates that rodent toxicology studies only predict 43% of human toxicities [28]. The use of nonrodents (i.e., nonhuman primates or dogs) improves the predictivity (63%) somewhat, while the combination of both rodents and nonrodents provides only 71% predictivity [28]. These results, however, are misleading in that compounds that induce an unacceptable level of toxicity in animals will never reach the clinic for evaluation in humans. As a result, many drugs may be unnecessarily halted in development due to toxicities in animals that are not relevant to humans. However, findings in animal toxicology studies are assumed to be predictive of human toxicity unless proven otherwise. Further exacerbating the challenge in bringing safe and effective therapeutics to the market is the increasingly competitive landscape in the pharmaceutical industry, and the number and types of studies necessary to demonstrate a new drug is sufficiently more efficacious and safe than standard care or otherwise provides additional value over current therapies.

In response to these challenges of late-stage attrition, the industry has taken steps to develop, evaluate, and implement new technologies and biomarkers at earlier stages in the drug discovery pipeline to shift attrition upstream in the process and before formal development begins [29]. By considering toxicity at an earlier stage, compound selection criteria can be applied to avoid further efforts on compounds destined for failure. Additionally, medicinal chemistry has an opportunity to make appropriate changes to the molecule to improve its characteristics and limit potential hazards. A combination of *in silico*, *in vitro*, and *in vivo* approaches judiciously applied at early stages of discovery has the potential to shift attrition-based decisions upstream in the process where corrective action can be implemented at lower costs (Fig. 8.1). It is here that predictive tools such as toxicogenomics have been applied to select safer clinical candidates and rapidly identify mechanisms of toxicity to aid in early human risk assessment.

8.1.4 Use of Toxicogenomics for Predicting Toxicity

The use of toxicogenomics for predicting toxicity is based on the hypothesis that changes in gene expression precede the microscopically observed tissue damage. Efforts to identify gene expression changes that precede and ultimately predict the onset of tissue damage have focused on the liver, kidney, and heart (Table 8.1). This likely reflects the greater incidence of drug-induced toxicities in these organs, in addition

Figure 8.1 Application of toxicogenomics during drug discovery. At the screening stage, very little compound is available to support direct experimentation and toxicogenomics. At the hit to lead stage, a more thorough characterization of the compounds is undertaken to identify potential off-target toxicities. Cell-based toxicogenomics experiments could be used to differentiate and prioritize lead scaffolds to direct resources toward scaffolds that have less safety hazards before initiating more resource-intensive *in vivo* studies. At the lead optimization stage, medicinal chemistry attempts to modify the lead scaffold to improve a variety of features. At this stage, toxicogenomics approaches can be used to further characterize and predict potential hazards that may emerge under longer-term dosing conditions. Once compounds reach preclinical development, investigative toxicogenomic experiments can be used to understand the mechanism of unanticipated toxicities and develop counter-screens to aid subsequent efforts.

TABLE 8.1 Examples of Studies Designed to Identify and Validate Predictive Genomic Biomarkers of Organ Toxicity in Rats

Predicted Endpoint	Species	Study Design	References
<i>Hepatotoxicity</i>			
Various liver pathologies (necrosis, cholestasis, and steatosis)	Rat	6-h to 14-d oral repeat dose	Steiner <i>et al.</i> [30]
Oxidative stress/peroxisome proliferators/macrophage activators	Rat	24-h single oral dose	McMillian <i>et al.</i> [31]
Acute hepatotoxicity	Rat	24-h single oral dose	Zidek <i>et al.</i> [32]
<i>Nephrotoxicity</i>			
Proximal tubular toxicity	Rat	7-d oral repeat dose	Thukral <i>et al.</i> [33]
Renal tubular toxicity	Rat	28-d oral repeat dose	Fielden <i>et al.</i> [34]
Renal tubular toxicity	Rat	28-d oral repeat dose	Kondo <i>et al.</i> [35]
<i>Cardiotoxicity</i>			
Cardiomyopathy	Rat	7-d intraperitoneal dose	Brown <i>et al.</i> [36]

to a number of well-described mechanisms of toxicity in these organs. Experimental approaches typically utilize tissues from rats following short-term (i.e., 24 h to 14 days of repeated daily drug administration) treatment to identify gene expression changes in target tissues that precede the histological appearance of tissue injury. These putative biomarkers are then evaluated independently against other toxicants and negative

controls with the goal of evaluating how accurately the biomarker can diagnose or predict the pathological event. While histological identification of tissue injury will remain the gold standard for evaluating drug-induced toxicity, the ability to predict the onset of tissue injury before it is observed microscopically can aid in the early identification (approximately in days and weeks) of toxic effects that may not manifest until longer-term studies (approximately in months and years) are conducted. As a result, toxicogenomics can be applied in the early stages of lead candidate selection as a means of predicting tissue injury or identifying hazards that may not manifest until longer duration and more resource-intensive toxicology studies are conducted to support clinical development. In addition to predicting toxicity, gene expression changes have often been shown to coincide with tissue damage and can be used to understand the mechanism of action (see below), in addition to confirming the diagnosis of toxicity made with traditional endpoints. This is valuable during early screening toxicity studies when it is often difficult to ascribe a histological finding as being treatment related when the incidence or severity is low and the number of animals per group is necessarily limited. While toxicogenomics is not viewed as a replacement for traditional endpoints such as clinical and anatomic pathology, it may be able to differentiate multiple compounds on the basis of predicted toxicity where traditional methods may not. This can help support the selection of clinical candidates for subsequent testing and ultimately shift attrition upstream in drug discovery.

8.1.4.1 Predicting Hepatotoxicity. One of the most frequently used biomarkers for hepatic injury, both clinically and preclinically, is the elevation of alanine aminotransferase (ALT) activity in the serum. ALT is a cytosolic enzyme expressed selectively in hepatocytes and is released into the blood following the loss of membrane integrity as a result of drug-induced hepatic necrosis. The value of measuring serum ALT elevation for diagnosing hepatotoxicity is that the test is noninvasive, easy to measure, and a direct consequence of cell damage. However, the major limitation of this biomarker is that it is rather insensitive, as an elevation in serum ALT activity is not detected until after a sufficient level of cell damage has occurred. Premonitory signals in the liver are needed that can identify subpathological damage before histological evidence. This would permit the prediction of hepatotoxicity in longer-term studies based on short-term animal studies. Thus far it has been difficult to identify a single predictive biomarker, or group of biomarkers, that has general applicability to predict longer-term hepatotoxicity.

Zidek *et al.* [32] utilized oligonucleotide microarrays containing a focused set of liver-expressed genes to identify the expression changes that preceded the onset of histological injury. The predictive screen utilized rats that were dosed with a number of well-known hepatotoxicants, such as carbon tetrachloride and acetaminophen, and negative controls that are not hepatotoxic. Livers were evaluated for gene expression 6, 24, and 72 h following a single dose. After 24 h, hepatic gene expression was able to differentiate the hepatotoxicants from the nonhepatotoxicants, even though the livers were histologically normal at this early time point. The putative biomarker genes were associated with functions well known to be involved in the hepatic stress response, thus providing a degree of biological plausibility to support these genes as predictive biomarkers. While this study confirms that gene expression changes can precede the development of histological evidence of drug-induced toxicity, it does not address the need for being able to predict liver damage that occurs only after longer-term

dosing (i.e., weeks or months). Predicting toxicity that occurs only a few days after the biomarker signal provides only marginal practical benefit in terms of addressing late-stage attrition. It may serve to increase the sensitivity for detecting toxicity where single-dose acute rat toxicity studies are utilized for screening; however, this approach is not routinely utilized.

While the prediction of long-term toxicity may be challenging, a number of studies do support the early assessment of a compound's mode of action, which may be useful in the selection or prioritization of compounds for further study. For instance, Thomas *et al.* [37] first demonstrated that hepatic transcript profiles from mice treated with 24 prototypical toxicants from five different modes of action classes could be accurately distinguished from each other. Similar work by Hamadeh *et al.* [38] confirmed that hepatic transcript profiles can correctly distinguish peroxisome proliferators from enzyme inducers. Subsequent publications extended these initial observations with bigger data sets and additional classes, including oxidative stress [39], and various hepatic pathologies including cholestasis, necrosis, and steatosis [30,40]. While this classification provides information on the potential mode of action, it is not a formal prediction and the degree to which these classifications predict longer-term outcomes is unproven. Nonetheless, understanding a compound's mode of action can aid in the early risk assessment since some modes of action, such as oxidative stress, are inherently more hazardous and could lead to cell damage under longer-term dosing or when combined with other precipitating factors. Understanding the mode of action can also be used to guide the selection and application of *in vitro* or cell-based counter-screens for lead optimization.

8.1.4.2 Predicting Carcinogenicity. Carcinogenesis is a common adverse outcome for chemicals and drugs tested in the two-year rodent bioassay, and the most frequent target organ for chemical-induced tumors in rodents is the liver [41]. However, while many compounds increase the incidence of liver tumors in mice and rats, the findings are often not relevant to human risk because of the high doses used in the two-year rodent bioassay or the unique mechanism of action of the drug in rodents [42]. While all known agents that are carcinogenic to humans can be shown to be carcinogenic in rodents, the converse is not always the case. Therefore, the carcinogenicity findings in rodents must be assessed for their relevance to humans based on the level of exposure, duration of exposure, and the mechanism of action of the drug.

It is well understood that direct-acting genotoxic compounds present a significant risk for carcinogenicity across species. Therefore, drugs are efficiently screened early in drug discovery for their ability to mutate DNA. Compounds that cause chromosomal damage are also screened early in drug discovery to avoid potential carcinogenic risks. Numerous attempts have been made to develop *in vitro* and alternative short-term or medium term *in vivo* assays that attempt to provide a less resource-intensive means of identifying chemicals with the potential to induce tumors through nongenotoxic mechanisms [43–45]. Despite these significant efforts, there are no well-validated assays available that reliably predict the ability of nongenotoxic compounds to cause cancer. As a result, it is often not until very late in development when the two-year rodent bioassay is performed that cancer liabilities emerge as a result of nongenotoxic mechanisms of action.

The carcinogenic activity of many nongenotoxic agents can have species, strain, and tissue specificity, thus making human risk assessment a challenge. Furthermore,

a number of carcinogenic modes of action in rodents are not relevant for humans owing to species-specific effects and the high doses often used in rodent studies. However, compounds that cause hormonal perturbation (e.g., increased prolactin levels) [46] or immunosuppression (e.g., cyclosporine) [47] could be carcinogenic to humans under certain conditions of exposure. As a result, it is important to not only determine the potential for carcinogenicity but also understand the mode of action in order to extrapolate the findings and assess human risk.

Carcinogenicity in rodents has been well studied with toxicogenomics, and a number of publications have attempted to identify early gene expression changes that are predictive of tumor outcome in a two-year rodent bioassay (Table 8.2). Most studies have focused on predicting carcinogenicity induced by nongenotoxic mechanisms of action; however, other efforts have focused on differentiating genotoxic from nongenotoxic modes of action both *in vitro* and *in vivo* [48–51]. The underlying premise of using toxicogenomics for carcinogenicity prediction is that the gene expression changes in the liver or target tissue precede and presumably contribute to tumor development. If so, these expression changes can be detected following short-term *in vivo* exposure and predict longer-term carcinogenic outcome after chronic dosing. While such a prediction would likely not obviate the need for a two-year rodent bioassay without further validation, the advanced knowledge may contribute to compound selection before development or lead to the initiation of critical investigative studies that begin to understand the mode of action of the drug to aid in human risk assessment. This has the potential to avoid lengthy delays as a result of investigative studies that would only ensue following the detection of a cancer risk at very late stages of drug development.

Early experiments using microarrays and other genome-wide expression profiling technologies focused on the identification of single genes as predictive biomarkers of carcinogenicity. Although certain genes could be identified as being significantly and reproducibly induced by carcinogenic chemicals, they were found not to be specific to carcinogens [53]. Instead, unique patterns of multiple genes were found to be necessary to differentiate carcinogenic from noncarcinogenic compounds, and it was quickly appreciated that no single gene by itself could adequately predict a heterogeneous class of compounds that cause tumors by diverse mechanisms [53,55].

With the availability of large gene expression databases of well-known carcinogenic compounds and negative controls (i.e., compounds that do not induce carcinogenicity), it was feasible to use supervised classification algorithms to identify multiple-gene biomarkers, or signatures, that were able to classify compounds as being carcinogenic or not. One of the first comprehensive efforts to identify a gene expression signature to predict carcinogenicity was by Nie *et al.* [56]. Using cDNA microarray data generated from the livers of Sprague-Dawley rats treated with a single dose of one of 52 compounds for 24 h, Nie *et al.* identified a set of 6 biomarkers that correctly predicted 89% of the compounds when evaluated by crossvalidation. Subsequent testing on independent samples verified that the signature could predict other nongenotoxic carcinogens. The utility of this signature for predicting nongenotoxic compounds that induce tumors in tissues outside the liver has not been widely tested, although preliminary results indicate it may have potential. While mechanisms of cell transformation are likely to be tissue specific, the liver may respond at the gene expression level to physiological or pathological changes in other tissues by virtue of its vital role in detecting and regulating changes in systemic metabolism.

TABLE 8.2 Summary of Toxicogenomic Studies Focused on the Identification and Validation of Genomic Biomarkers of Carcinogenicity

Prediction Endpoint	Species	Genomic Technology	Study Design	References
Liver tumor promotion	Rat	Subtractive cDNA hybridization	Modified Ito medium term rat liver bioassay	Shibutani <i>et al.</i> [52]
Genotoxic and nongenotoxic carcinogens	Mouse	Custom cDNA microarray	14-d and 1-, 3-, and 6-mo dietary exposure	Iida <i>et al.</i> [53]
Genotoxic carcinogens	Rat	Affymetrix RGU34A oligonucleotide array	14-d oral repeat dose	Ellinger-Ziegelbauer <i>et al.</i> [48]
Genotoxic and nongenotoxic hepatocarcinogens	Rat	Incyte Rat GEM 1.0 cDNA microarray	5-d oral repeat dose	Kramer <i>et al.</i> [54]
Genotoxic and nongenotoxic carcinogens	Rat	Affymetrix RGU34A oligonucleotide array	14-d oral repeat dose	Ellinger-Ziegelbauer <i>et al.</i> [49]
Genotoxic versus nongenotoxic carcinogens	Mouse	Agilent Mouse Oligo array	14-d dietary exposure	Iida <i>et al.</i> [55]
Nongenotoxic carcinogens	Rat	Custom cDNA microarray	Single dose	Nie <i>et al.</i> [56]
Liver and lung carcinogens	Mouse	Affymetrix 430 v2.0 oligonucleotide array, serum NMR	90-d oral repeat dose	Thomas <i>et al.</i> [57]
Lung carcinogens	Mouse	Affymetrix 430 v2.0 oligonucleotide array	90-d oral repeat dose	Thomas <i>et al.</i> [58]
Nongenotoxic hepatocarcinogens	Rat	Codelink RU1	5-d oral repeat dose	Fielden <i>et al.</i> [59]
Genotoxic and nongenotoxic hepatocarcinogens	Rat	Affymetrix RAE230A oligonucleotide array	14-d oral repeat dose	Ellinger-Ziegelbauer <i>et al.</i> [60]
Nongenotoxic hepatocarcinogens	Rat	Affymetrix RAE230A oligonucleotide array	28-d oral repeat dose	Uehara <i>et al.</i> [61]
Lung carcinogens	Mouse	Affymetrix 430 v2.0 oligonucleotide array	90-d repeat dose exposure (oral, feed, and inhalation)	Thomas <i>et al.</i> [62]

Similar studies reported by Fielden *et al.* [59] have demonstrated the utility of a large gene expression database for generating and validating hepatic gene expression signatures for the prediction of nongenotoxic hepatocarcinogenicity in rats. To adequately test the accuracy of the model, the signature was tested against hepatic gene expression data from rats treated for up to 5 days with 47 independent compounds distinct from those used in the training set. This resulted in a sensitivity of 81% and a specificity of 84%. By comparison, the signature was superior in accuracy relative to more traditional endpoints that have previously been proposed and evaluated as predictors of liver tumors, including hepatomegaly, hepatocellular hypertrophy, necrosis, serum ALT activity, and induction of cytochrome P450 genes [63,64]. In addition, the gene expression profile of the test compound could be compared against nongenotoxic carcinogens of known mode of action in order to provide hypotheses as to its mode of action. Such compounds include P450 inducers, peroxisome proliferators, steroidal compounds with estrogenic and androgenic activity, and hepatotoxic carcinogens. These results indicate that hepatic gene expression data from short-term rat studies can be used not only to predict nongenotoxic hepatocarcinogens but also to understand a compound's mode of action to aid human risk assessment.

In addition to the many studies investigating the prediction of hepatocarcinogenicity, other work suggest that lung gene expression data from subchronic toxicology studies can also predict lung tumor outcome in the two-year rodent bioassay [58,62]. Initial efforts were focused on evaluating the relative utility of gene expression data and metabolomic data for predicting either liver or lung carcinogenicity in 90-day repeat-dose studies in mice [57]. This study utilized a number of environmental chemicals, including both genotoxic and nongenotoxic chemicals. Results from this study indicated that individual genes or metabolites were not highly predictive; however, the overall profiles did classify carcinogens and noncarcinogens. However, this study utilized a small number of chemicals, and it was not until a larger study using 13 diverse chemicals that a signature was developed and more broadly tested [58]. Subsequent work by the same group extended these initial findings to a larger set of compounds and provided a more thorough characterization of the signature and its ability to predict lung carcinogenicity, its dose dependency, and the effect of experimental variables on assay performance [62]. In contrast to previous efforts, these studies of lung carcinogenicity relied on lung gene expression from mice exposed for 90 days. While this approach would not identify carcinogens from short-term screening studies typically used in early drug discovery, it is practical in the sense that 90-day toxicology studies are often performed on chemicals in advance of longer-term chronic and lifetime rodent bioassays. Therefore, genomic results could be incorporated into these standard testing paradigms and provide prediction in advance of a lengthy two-year carcinogenicity study. As a result of using this later time point for signature generation and application, it is likely that these signatures are detecting gene expression changes that reflect neoplastic transformation rather than mechanistic events that are linked with carcinogenicity. This may provide a more robust predict of the likelihood of lung tumors in longer-term studies and their relationship to dose. However, it may not readily lead to an understanding of a compound's mode of action to enable human risk assessment and would not provide an early prediction (i.e., less than two weeks) in advance of more resource-intensive toxicology studies.

8.1.5 Use of Toxicogenomics to Understand Mechanisms of Toxicity

Although the interpretation of toxicity endpoints in preclinical studies is usually well understood, the predictivity of the findings in animal models for humans is often not clear. This could be due to underlying differences in pathophysiology between species, as well as due to differences in pharmacokinetics and drug metabolism. A number of examples have been reported demonstrating rodent-specific toxicities due to differences in drug metabolism [65], hormonal regulation [66], or mechanisms of tumor formation due to high dose tissue accumulation [67]. Chemical-induced toxicity in animals is often observed in routine screening studies during lead optimization; however, when the mechanism of toxicity and its relevance to humans is unknown, the development of that compound is typically stopped in the interest of time and resources in order to focus efforts on identifying additional compounds free of that liability. However, by understanding the mechanism of toxicity in susceptible animal models, a risk assessment can be made to understand the relevance of the finding in humans. In addition, the knowledge obtained by a thorough understanding of the mechanism of toxicity can be used to guide the application of *in vitro* assays or *in vivo* biomarkers. These can be applied to screen additional molecules and identify the offending toxicophore in order to design future chemicals that are devoid of the liability. Improvements to human risk assessment and the selection of the right drug candidates for clinical development are not made by conducting long-term toxicity studies earlier in drug discovery, but by obtaining a deeper understanding of the mechanisms of toxicity before conducting human studies. With that in mind, we now consider how toxicogenomics can contribute to an understanding of common mechanisms of liver toxicity.

8.1.5.1 Hepatomegaly and Hepatocellular Hypertrophy. Microarray analysis can be used to elucidate mechanisms of toxicity based on the fundamental concept that drug-induced toxicities are accompanied by gene expression changes mechanistically linked to the toxicity. Furthermore, compounds with a common mechanism of toxicity will produce similar gene expression changes and their profiles should cluster together and should be distinct from compounds inducing a similar toxicity but through different mechanisms. However, the identification of such distinct gene- and pathway-based information should not be taken as the final endpoint in identifying the mechanism but rather should be used in conjunction with histopathology and/or clinical pathology data for hypothesis generation, followed by additional biochemical or cell-based investigations to confirm the hypothesis. Once discriminating gene expression changes or “signatures” have been identified and validated, they can be used to classify unknown toxicants to understand their mechanism of toxicity.

An increase in liver weight, or hepatomegaly, is a frequent observation in preclinical rodent toxicologic studies. Increased liver weight can be caused by a number of mechanisms, including an increase in the number of cells (hyperplasia) or an increase in hepatocyte size (hepatocellular hypertrophy). Hyperplasia is of obvious concern for tumor formation; however, hepatocellular hypertrophy is a common adaptive response of the liver to xenobiotics or other metabolic challenges or stimuli [68,69]. In response to xenobiotics, the liver induces a characteristic spectrum of drug-metabolizing enzymes. This may be of significance for drug–drug interactions and pharmacokinetics. By contrast, the liver responds to fatty acids by increasing enzymes

involved in their metabolism. This is often of no toxicological significance for humans. Therefore, it is important to understand the mechanism underlying the increase in liver weight and hypertrophy.

Early toxicogenomic studies established that gene expression data from livers can be used to differentiate distinct mechanisms of hepatocellular hypertrophy induced by different chemicals. For example, analysis of rat liver tissues from animals treated with two classes of compounds leading to hepatomegaly and hepatocellular hypertrophy through different mechanisms resulted in distinct gene expression signatures [38]. Treatment with a peroxisome proliferator (Wyeth 14643, gemfibrozil, or clofibrate) or the enzyme inducer phenobarbital resulted in hepatocellular hypertrophy with minor histological differences between the classes after two weeks of treatment. However, only 24 h after treatment, the two classes of compounds demonstrated distinct gene expression profiles with the peroxisome-proliferator-treated samples clustering together and distinct from the phenobarbital-treated liver samples. Additionally, the observed gene expression changes were related to previously described metabolic, pharmacologic, and toxicologic effects of the compounds, thus providing relevant mechanistic information. While the peroxisome-proliferator-treated livers had increased expression of genes involved in triglyceride hydrolysis, fatty acid uptake, oxidation, and conversion to acyl CoA derivatives, phenobarbital treatment resulted in increased cytochrome P450 genes, microsomal epoxide hydrolase, glutathione transferases and a decrease in carnitine palmitoyltransferase 1 mRNA. Further investigation was performed to determine if the peroxisome-proliferator- and phenobarbital-specific gene signatures could be used to classify blinded samples based on the mechanism of toxicity of the compound [70]. Using the previous peroxisome-proliferator- and phenobarbital-treated livers as a training set, a group of 22 highly discriminatory genes were identified. These were then used to successfully classify blinded liver samples from phenytoin-, diethylhexyl phthalate-, and hexobarbital-treated rats as having a similar mechanism of action to phenobarbital, peroxisome proliferators, and neither, respectively.

These studies, along with others, helped establish that toxicogenomic analyses can be used to identify gene expression changes causally linked to a phenotypic endpoint. Although both the peroxisome proliferators and enzyme inducers result in hepatocellular hypertrophy, they produced distinct gene expression changes that could be used to differentiate between the mechanisms leading to the same phenotype. However, one must be cautious in interpreting results and in dissociating causal gene expression changes from associative changes through further investigation or consideration of other evidence. Additionally, a given toxicity may be driven by multiple mechanisms with different implications for human risk. Differentiation between peroxisome proliferators and enzyme inducers as described above may have implications for the clinic as it is often desirable to avoid enzyme inducers due to the potential for drug–drug interactions in humans. By contrast, hepatocellular hypertrophy induced by peroxisome proliferators is typically considered to be rodent specific and without relevance to humans [71,72]. Thus, gene expression signatures can be used to guide compound selection early in discovery as well as aid in the interpretation of preclinical effects, such as hepatocellular hypertrophy, and their relevance to humans.

8.1.5.2 Hepatotoxicity and Cholestasis. Drug-induced hepatotoxicity is a major hurdle in drug development and accounts for many adverse drug reactions and black box warnings in marketed drugs. Examination of terminated clinical development

projects from 1992 to 2002 found that 43%, 25%, and 35% of drugs in phases I, II, and III, respectively, were terminated as a result of toxicity, with many of these compounds classified as hepatotoxicants [73]. The susceptibility of the liver to toxicity can be partially attributed to its exposure to relatively high concentrations of drugs as a result of portal vein exposure following intestinal absorption, as well as its critical role in drug metabolism and clearance.

The liver is particularly susceptible to disruption of bile flow, which can result in cholestasis and liver injury. The liver is responsible for the synthesis of bile salts from cholesterol precursors, some of which are recycled via uptake at the basolateral membrane of hepatocytes adjacent to the portal blood supply. Hepatic uptake of bile salts primarily occurs via the sodium-dependent transporter sodium-taurocholate cotransporting polypeptide (Ntcp; *Slc10a1*) and to a lesser degree by a family of sodium-independent anion-transporting polypeptides (Oatps; *Slcos*). Canalicular excretion of biliary constituents such as bilirubin, xenobiotics, and bile salts also occurs through transporters such as the bile salt export pump (Bsep; *Abcb11*), the multidrug resistance-associated protein-2 (Mrp2; *Abcc2*), multidrug resistance-1 (Mdr1; *Abcb1*), and Mdr3 (*Abcb4*) [74]. Inhibition of Bsep, the primary bile salt efflux transporter, can lead to increased intracellular levels of bile salts, which are cytotoxic to hepatocytes at elevated concentrations. In fact, drug-related disruption of Bsep function is implicated in liver injury associated with many marketed and withdrawn drugs such as bosentan, glyburide, and erythromycin estolate [75–77]. Given that preclinical species are generally considered to be poor models of human liver injury related to Bsep inhibition, it can be difficult to preclinically predict Bsep-inhibition-mediated liver injury [75,78]. However, toxicogenomic monitoring of bile acid signaling pathways has the potential to be useful in identifying obstructions of bile flow, such as those caused by drug-induced Bsep inhibition. In particular, increased intracellular bile acid levels can lead to adaptive responses leading to altered transcription of bile acid synthesis genes and hepatocellular transporters. These gene expression changes are mediated by one or more nuclear receptors and can be monitored through gene expression analyses. For example, activation of the farnesoid X receptor (FXR) by bile acids results in decreased expression of the cytochrome P450 genes *Cyp7a1* and *Cyp8b1*, as well as the hepatocellular uptake transporter Ntcp leading to decreased bile acid synthesis and hepatocellular uptake, respectively [74,79,80]. Gene induction is also observed for Bsep and Mrp2, which serve to increase canalicular and basolateral efflux of bile acids [81–83]. Additional nuclear receptors such as the PXR and CAR also serve to regulate expression of bile acid synthesis, metabolism, and transport genes such as *Cyp3a4* and *Oatp2* (Fig. 8.2) [74]. Microarray analysis of livers from rodent bile duct ligation models of obstructive cholestasis confirms altered gene expression of bile-acid-related genes such as decreased *Ntcp* and *Cyp8b1* [84,85].

Monitoring expression of genes involved in bile acid synthesis, metabolism, and transport in preclinical models can provide important information regarding bile flow obstruction. However, as with most toxicogenomic studies, inference regarding the mechanism of cholestasis must be done cautiously, as there are many confounding factors and conditions that may result in similar responses or can mask these diagnostic expression changes. For example, a compound may directly activate PXR and/or CAR, thus resulting in altered expression of bile-acid-related genes in a manner similar to what would be expected from Bsep inhibition. Inflammation has also been documented to alter transcription of hepatocellular transporters. For example, endotoxin

Figure 8.2 Transcriptional regulation of bile acid synthesis and hepatocellular transporters. Cholesterol activation of liver X receptor (LXR) mediates transcription of *Cyp7a1* and *Cyp8b1*. Bile acids upregulate transcription of hepatocellular transporters and inhibit their own synthesis via the activation of PXR and FXR. *Source:* Figure modified from Trauner and Boyer [74].

and interleukin-1 β have been shown to downregulate transcription factors, resulting in decreased Ntcp and Mrp2 expression [74,86]. In the case of inflammation-induced decreases in bile acid transporter genes, toxicogenomic data may provide evidence pointing to an inflammatory response such as altered expression of cytokines or acute phase proteins such as albumin or fibrinogen. In order to determine mechanisms related to transporter inhibition or nuclear receptor activation, one can supplement the *in vivo* toxicogenomic data with *in vitro* assays such as a Bsep inhibition or nuclear receptor activation assay. These assays can be used to measure potency on these off-targets, which can help rank and prioritize compounds for testing and guide medicinal chemistry efforts to avoid these off-target effects. Thus, toxicogenomics can be utilized early in drug discovery in conjunction with additional assays in order to monitor hepatocellular transporter changes indicative of transporter inhibition and cholestatic conditions. This information can help drug discovery teams evaluate the risk to humans and select appropriate drug candidates to be advanced to clinical studies.

8.1.5.3 Oxidative Stress and Reactive Metabolite Formation. Oxidative stress occurs when pro-oxidants such as reactive oxygen species (ROS) exceed the capacity of a cell's antioxidant systems to detoxify the ROS. When this occurs, it increases the risk of cellular damage and associated pathologies [87–90]. Generation of oxidative species such as the superoxide anion, hydrogen peroxide, and the hydroxyl radical occurs through the reduction of molecular oxygen. This can occur through both endogenous processes such as oxidative phosphorylation, the inflammatory respiratory burst, cytochrome P450 metabolism, and peroxisome proliferation as well as exogenous sources including xenobiotics that undergo redox cycling and metals that participate in the Fenton reaction. Production of cellular ROS is then counterbalanced by the cellular antioxidant defense systems such as superoxide dismutase, glutathione transferase, and vitamins E and C. However, when cellular oxidants exceed the antioxidant defense system, oxidation of DNA, proteins, and lipids can occur. This would disrupt vital cellular processes and could ultimately lead to cell death. Additionally, formation of the reactive drug metabolites during metabolism or redox cycling of a chemical can lead to protein and DNA adducts. This too can lead to disruption of cellular process and cell death. Protein–drug adducts can also serve as

antigens and precipitate an adverse immune response [91–93]. Therefore, detecting the ability of a chemical to induce an oxidative stress response *in vivo* can be used to identify potential hazards that could be relevant to humans.

Given the liver's role in energy and xenobiotic metabolism and the high exposure to drug via the portal vein, the liver has an increased susceptibility to oxidative stress and reactive metabolites formed by metabolic bioactivation. The resulting cellular damage can ultimately manifest in altered clinical chemistry endpoints such as increases in serum transaminases. However, drugs can lead to increased oxidative stress through different mechanisms, each with different consequences for human risk. Unfortunately, standard endpoints such as histopathology and clinical chemistry do not provide mechanistic information. For example, oxidative stress can be a result of macrophage activation, secondary to peroxisome proliferation, or due to the generation of free radicals or reactive metabolites. Drug-induced macrophage activation or endotoxin leakage through a damaged gastrointestinal tract, as demonstrated by certain nonsteroidal anti-inflammatory drugs, leads to the production of ROS as a defensive response [94–96]. By contrast, peroxisome-proliferator-activated receptor α (PPAR α) agonism is typically followed by an oxidative stress response that is considered to be a normal physiological response to increased oxidative metabolism [97,98]. Reactive drug metabolites can lead to oxidative stress through redox cycling or free radical generation. This can overwhelm the endogenous antioxidant supply and lead to cell death. Therefore, early differentiation between these mechanisms is beneficial in decision making during drug discovery.

Analogous to the application of gene expression profiles to distinguish mechanisms of hepatocellular hypertrophy, gene expression signatures have been shown to differentiate mechanisms of oxidative stress. McMillian *et al.* [31,39,99] describe a toxicogenomic analysis of a collection of 50 in-house proprietary compounds and 100 paradigm compounds. This analysis facilitated the identification of distinct liver gene expression signatures from known peroxisome proliferators, macrophage activators, and reactive metabolite generators. The signatures were then used to categorize additional unknown compounds on the basis of their gene expression profiles. For example, the macrophage activator signature generated from lipopolysaccharide and zymosan A clustered together with compounds such as carbon tetrachloride, allyl alcohol, and galactosamine, which have previously been reported to activate macrophages in rat liver. As one may expect, the macrophage activator signature contained genes mechanistically linked to macrophage activation, such as acute phase response and immune activation genes, in addition to genes related to endoplasmic reticulum stress and chaperone genes. Interestingly, some of the genes regulated by the macrophage activators were observed to be inversely regulated by the PPAR α compounds. Similarly, the reactive metabolite signature contained many genes regulated by the nuclear factor-like 2 (Nrf2) transcription factor, which included many antioxidant and phase II metabolism genes. Selection of a subset of these genes such as NAD(P)H dehydrogenase (Nqo1), glutathione transferase μ type 2, heat shock protein 90 α , and glutamate–cysteine ligase led to the separation of a majority of the reactive metabolite compounds from compounds of the other classes [31,39,99]. Studies such as these clearly demonstrate that there are distinct transcriptional changes associated with the treatment of compounds that induce oxidative stress by different mechanisms. Furthermore, many of these genes are linked to the mechanism rather than just associative. In addition, new mechanistic insight can be gained through observation of previously unreported gene expression

changes, such as with the macrophage activator induction of endoplasmic reticulum stress-related genes and the inverse regulation of genes by macrophage activators and PPAR α agonists.

8.1.6 Use of Toxicogenomics to Understand Hepatic Drug Metabolism

Exposure to xenobiotics, whether via diet, environmental exposure, or prescription and over-the-counter drugs, can lead to enzyme induction in the liver and other organs. Xenosensors such as the nuclear receptors PXR and CAR, as well as the aryl hydrocarbon receptor (AhR), are critical mediators of defense against xenobiotics and can all mediate distinct and sometimes overlapping patterns of xenobiotic-induced enzyme induction. Upon receptor activation, there is an induction of numerous phases I, II, and III metabolism enzymes and transporters that generally serve as an adaptive and/or protective mechanism for the organism to metabolize and eliminate the xenobiotic. However, in humans undergoing single or multiple drug therapies, enzyme induction through these various sources can cause altered drug metabolism leading to uninvited consequences. It has been reported that half of the drugs withdrawn from the US market between 1999 and 2004 were associated with drug interactions [100,101]. Clearance of the primary drug or a coadministered drug can be increased or decreased, or a prodrug can be activated at altered rates leading to altered pharmacokinetic and pharmacodynamic effects. It is also well documented that enzyme inducers can exacerbate or lead to new toxicities of drugs by enhancing or initiating formation of a toxic metabolite. A classic example is ethanol-induced CYP2E1 induction, which results in the increased formation of the reactive acetaminophen metabolite, *N*-acetyl-*p*-benzoquinone imine. Enzyme induction can also alter metabolism of endogenous compounds, leading to deleterious effects. This is the case of individuals undergoing long-term treatment with enzyme inducers. For example, long-term induction of CYP3A4 can lead to increased metabolism of the active metabolite of vitamin D₃, 1 α , 25-dihydroxyvitamin D₃, thus causing vitamin D deficiency and osteomalacia [102]. Even in a more controlled environment such as preclinical drug development, enzyme induction can lead to undesirable effects such as reduced drug exposure after repeated doses (i.e., autoinduction) due to induction of the enzyme responsible for its own metabolism or clearance. It may also lead to enhanced toxicity when the metabolism enzymes bioactivate the drug or enhance clearance of endogenous molecules, such as steroid hormones. As a result of these potential interactions and effects on hepatic drug metabolism, the ideal drug candidate is one that does not affect cytochrome P450 levels or activity. The US Food and Drug Administration (USFDA) has also recommended that candidate drugs be assessed for induction or inhibition of major cytochrome P450s to determine the potential for metabolic interactions [101]. Thus, early understanding of enzyme induction in preclinical drug development can help in the design of preclinical studies and in the prediction of potential issues that may arise in humans.

8.1.6.1 PXR, CAR, and AhR. PXR and CAR are both members of the nuclear receptor family 1 and are expressed predominantly in tissues highly exposed to xenobiotics, such as those of the liver and small intestine. Upon ligand binding, PXR forms a heterodimer with the retinoid X receptor (RXR) and binds xenobiotic response elements in the promoters of target genes, leading to increased transcription. CAR-mediated transcription occurs in a similar manner with the exception that CAR

resides in the cytoplasm and undergoes nuclear translocation upon ligand binding and activation [103]. Activation of PXR and/or CAR leads to the induction of mRNA, protein, and enzyme activity for a number of xenobiotic metabolism enzymes, including CYP3A4 and CYP2B1 in humans (Fig. 8.3). Activation of these receptors in rodents is also associated with hepatomegaly as a result of both hepatocellular hypertrophy and increased replicative DNA synthesis, resulting in hepatocyte proliferation. As a result, chronic exposure of rodents to PXR or CAR agonists, such as chlordane or phenobarbital, is also associated with liver tumor formation [68,69,104]. In humans, however, there is no evidence to indicate that PXR or CAR activation is associated with an increased risk for liver tumors [68,105,106]. Investigation of phenobarbital or chlordane administration to humanized huPXR/huCAR mice confirmed that despite the enzyme induction, liver enlargement, and hepatocellular hypertrophy, there was no increase in replicative DNA synthesis and therefore no hepatocellular

Figure 8.3 (a) PXR activation leads to the transcription of phases I, II, and III xenobiotic metabolism and transporter genes. (b) Infections and inflammatory conditions can decrease the expression of xenobiotic metabolism genes induced by PXR activation. The pathway was generated through the use of Ingenuity Pathways Analysis (Ingenuity® Systems, <http://www.ingenuity.com>). Figure 8.3 (b) (Continued)

proliferation [68]. Despite there being no increased risk for liver tumors, activation of these nuclear receptors remains an area of interest in drug development because of the enzyme induction and potential to affect metabolism of other xenobiotics or endogenous molecules. Of particular importance in hepatic metabolism is the PXR-mediated induction of *Cyp3a* genes in rodents and *CYP3A* genes in humans as demonstrated by the prototypical rodent and human PXR activators pregnenolone 16α-carbonitrile and rifampicin, respectively [107]. CYP3A4 is one of the most abundant cytochrome P450 enzymes in human liver and accounts for the metabolism of approximately 50–60% of approved drugs [108,109]. Similarly, CAR activation leads to increased transcription of the classical CAR target genes *CYP2B* and *Cyp2b* in humans and rodents, respectively. In addition to cytochrome P450s, activation of

PXR and CAR leads to altered expression of phase II/III metabolism and transport genes such as sulfotransferases, UDP-glucuronosyltransferases (e.g., *Ugt1a1*), glutathione-*S*-transferases, *BSEP*, *NTCP*, and *MRP3* [7,110]. As with PXR and CAR, the AhR regulates the expression of xenobiotic metabolism genes including the cytochrome P450 genes *Cyp1a1*, *Cyp1a2*, and *Cyp1b1*, in addition to *Ugt1a1* and *Nqo1* [111,112]. The AhR is typically retained within the cytoplasm as a complex with heat shock protein 90, hepatitis B virus X-associated protein 2, and p23 [111,113,114]. Upon ligand binding, it undergoes nuclear translocation and heterodimerization with the AhR nuclear translocator followed by transcription of target genes [115]. Effects of exposure to the prototypical AhR ligand 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (i.e., TCDD) include hepatomegaly, hepatotoxicity, weight loss, immunosuppression, and liver tumors [116]. However, there are a number of weak AhR ligands, such as omeprazole and flutamide, that have been approved by the USFDA and do not exhibit TCDD-like toxicities in rats or humans [117]. Thus, as with PXR and CAR agonists, the major concern for drugs that are AhR agonists is the metabolic enzyme induction and potential for drug–drug interactions.

Toxicogenomics can be advantageous in the assessment of PXR, CAR, and/or AhR activation as microarrays can be used to measure the induction nuclear receptor target genes *in vitro* or *in vivo* as surrogate measures for receptor activation. For example, increased *Cyp3a*, *Cyp2b*, or *Cyp1a* expression can be considered markers of PXR, CAR, or AhR activation, respectively. The high content nature of microarray analysis allows for efficient screening of numerous genes in parallel, and when applied to *in vivo* preclinical models, it can permit the assessment of the effect of both the parent compound and any potentially active metabolites.

The mechanistic information derived from the evaluation of nuclear receptor target genes may aid in the development of more specialized assays to counter-screen additional chemicals, as well as provide data on structure–activity relationships to guide medicinal chemistry. However, understanding the specificity of nuclear receptor action is challenging owing to the complexities of gene regulation. For example, *in vivo* *Cyp1a1* induction may not be a specific marker of AhR agonism, and while it provides information regarding enzyme induction, additional information and assays may need to be considered to determine true AhR agonism [117]. Additionally, PXR and CAR can be activated by some of the same ligands, they have overlapping target genes, and they can also transcriptionally regulate each other, therefore making it difficult to determine what is controlling target gene expression [118,119]. Consequently, one may observe increased expression of both *Cyp3a* and *Cyp2b* in addition to other phase II metabolism genes, following administration of a candidate drug in a preclinical rodent study. While these observations are important for understanding the effects of the candidate drug on metabolism and possible changes in serum bilirubin or bile acid levels, more quantitative and specific methods such as real-time polymerase chain reaction (RT-PCR) analysis or cell-based nuclear receptor activation assays can be used to confirm findings based on microarray data.

There have been attempts to further identify nuclear receptor responsive gene sets that can then be used to assess individual nuclear receptor activation [120]. However, these studies do not take into account overlap or cross talk between pathways. For instance, other factors and conditions may confound interpretation of gene expression data, such as cholestasis or inflammation. Given that bile acids can be ligands for PXR, one may not be able to distinguish between PXR activation due to a cholestatic

condition or as a direct result of the drug itself. Inflammatory conditions and cytokines, on the other hand, have generally been accepted as suppressors of drug-metabolizing enzymes, possibly through the interaction of nuclear factor κ B with RXR α [121]. Therefore, a drug that leads to an increase in inflammatory cytokines, in addition to PXR or CAR activation, could lead to suppression of nuclear receptor target genes and a masking of the PXR- or CAR-mediated activity. It is also important to note that there are many species differences between nuclear receptor expression, ligands, and target genes, making it difficult to extrapolate drug–drug interaction risk from preclinical models to humans. While toxicogenomic data from *in vivo* preclinical models can be used to understand preclinical observations, it is best used in conjunction with human-specific nuclear receptor activation assays to guide clinical candidate drug selection.

8.1.7 Use of Toxicogenomics *In vitro* for Predicting Toxicity and Drug Metabolism

Applying toxicogenomics to cell-based systems represents another means of facilitating differentiation of compounds at a much earlier stage of drug discovery than *in vivo* testing would permit due to limited compound supply. Furthermore, it may offer the ability to predict *in vivo* toxicity as a means of ensuring that resources are allocated to chemical scaffolds that are least likely to be plagued by toxicity [122]. The use of toxicogenomics at this stage has not been as widely implemented because of the technical challenges of reproducibility and the questionable concordance to *in vivo* systems [123,124]. However, research in this area continues, and promising results in niche areas have demonstrated cases where toxicogenomics in cell-based systems can provide practical advantages when compared to *in vivo* models. An example of *in vitro* toxicogenomics is the prediction of phospholipidosis using human HepG2 cells [125,126].

The application of predictive toxicology models is limited not only by the degree of validation in the assays but also due to the practical need of synthesizing enough chemical material to perform *in vivo* studies, which often requires grams of material. As a means of shifting attrition even earlier in drug discovery, *in vitro* and cell-based methods are needed to take advantage of their adaptability to automation to enable higher throughput and their reliance on small amounts of test compound (approximately in milligrams). Toxicogenomics has been applied to studying drug-induced gene expression changes in a variety of cell models as a means of predicting *in vivo* toxicity or understanding mechanisms of action. Primary cells are often used because they are not transformed, as are continuous cancer cell lines, and thus maintain cellular activities more similar to cells in their native and intact tissue. However, transformed cell lines have also been evaluated, as they are easier to obtain and propagate. Comparisons of gene expression profiles of transformed, primary, and native tissues have revealed extensive differences in basal mRNA expression [123]. The differences are likely to be a result of environmental factors inherent to the culturing conditions, as well as the loss of multicellular interactions that are only obtained *in vivo*. In spite of these differences, certain drug-induced pharmacological and toxicological changes in gene expression have been shown to be reproduced *in vitro* [127]. Taking advantage of this, numerous groups have attempted to identify gene-expression-based biomarkers *in vitro* that accurately predict the ability of the compound to induce mechanisms of toxicity and pathological effects *in vivo*. Most of this work has focused on *in vitro*

cell-based models of liver and kidney toxicity owing to the importance of these tissues in drug-induced toxicity and the availability of well-characterized cell-based models.

To address the challenge of trying to recapitulate mechanisms of toxicity that may involve, or be augmented by, complex multicellular interactions *in vivo*, a number of researchers have attempted to utilize rat liver slices [128] or advanced culture models that incorporate cell–cell heterotypic interactions, perfusion flow, and three-dimensional interactions [129]. For example, liver slices have been utilized for mechanistic studies to understand the pathways relevant for the induction of liver fibrosis [130]. Although similarities in certain pathways of collagen formation were identified, other comparative studies have shown that *in vivo* models of hepatic fibrogenesis are more complex and not well represented by studying isolated hepatic stellate cells *in vitro* [131]. So while certain pathways may be reproduced in a variety of cell-based models, they fail to represent the full extent of signaling in the intact liver. As a result, the use of toxicogenomics in cell-based models is likely best reserved for studying the molecular consequences of perturbing known pathways in defined cell types, such as phospholipidosis in hepatocytes, rather than trying to fully recapitulate complex pathologies such as hepatic fibrosis.

Phospholipidosis is a lipid storage disorder that has the potential to lead to cellular necrosis. It can be confirmed only via electron microscopy, which is a time-consuming and expensive method and is not amenable to screening. To address this limitation and establish a more facile screening assay, Sawada *et al.* [125] utilized microarrays to identify gene expression changes in human HepG2 cells, a human hepatoma cell line, which would predict the induction of phospholipidosis. A number of compounds known to cause phospholipidosis *in vivo* were evaluated in cell culture for 72 h. The gene expression changes were then analyzed by microarrays to identify biomarkers that were specifically regulated by phospholipidosis-inducing compounds and not by other negative controls. A total of 17 candidate biomarkers were identified as being significantly increased or decreased in expression, and 12 of these were confirmed to be significantly changed by RT-PCR. To validate the predictivity of these biomarker genes, they were measured by RT-PCR following the treatment of HepG2 cells with an additional 14 test compounds with known phospholipidosis-inducing activity. Additionally, the changes in gene expression as measured on the microarray also suggested that alterations in lysosomal function and cholesterol metabolism may contribute to the development of this lipid storage disorder. Subsequent validation in independent laboratories confirmed the predictive nature of the signature in the same cell line [132,133]. This example demonstrates how *in vitro* expression profiling using microarrays can contribute to both a mechanistic understanding and a relatively quick and efficient means of screening compounds for a pathological effect. It is noteworthy to mention, however, that alternative and potentially higher throughput and more efficient *in vitro* methods to assess phospholipidosis in cell culture have been proposed [134]. While gene-expression-based endpoints are routine in modern molecular biology laboratories, they require multiple steps of RNA extraction, reverse transcription, and subsequent detection (microarray, PCR), and so they may not be the most economical and expeditious means of predicting toxicity.

In addition to phospholipidosis, other cell-based approaches have shown potential for predicting or mechanistically understanding a variety of pathologies. For example, gene expression profiling has been used in primary hepatocytes to differentiate compounds that do or do not induce steatosis *in vivo* [135]. Some efforts have also evaluated

cell-based assays and toxicogenomics as a means to predict hepatocarcinogenicity; however, the results suggest more work is needed to overcome limitations with system variability [136]. Nonetheless, efforts have demonstrated that genotoxic carcinogens can be differentiated from nongenotoxic carcinogens [50,51].

In order to study the mechanisms of nephrotoxicity, cell-based models such as rat primary renal cortical tubular cells are often used [137]. Consistent with other *in vitro* and *in vivo* genome-wide expression profiling experiments, nephrotoxicants clustered together and distinct from negative controls, which consisted of compounds known not to significantly affect kidney function *in vivo*. Cellular responses to stress were common. However, it is noteworthy that cisplatin, a nephrotoxic compound, and a structurally related analog carboplatin that is much less nephrotoxic *in vivo* produced a similar gene expression response regardless of dose or time. This indicates that a similar on-target effect was being recapitulated *in vitro*; however, the unique off-target effects of cisplatin that lead to toxicity were not readily detected in this cell model by gene expression. Alternatively, other extrinsic factors (cell–cell heterotypic interactions, humoral factors, etc.) are necessary to recapitulate the *in vivo* toxicity of cisplatin. Other researchers have utilized human renal tubular cell lines to study the mechanisms of nephrotoxicity of immunosuppressants such as cyclosporine and sirolimus [138,139]. New insights into mechanisms of action can be derived from well-controlled experiments; however, it has been shown that critical experimental variables can significantly impact the results when data is compared across different laboratories [138].

In addition to predicting *in vivo* toxicity and understanding mechanisms of toxicity, human and rat hepatocytes are used routinely for studying phases I and II drug metabolism and mechanisms of drug–drug interactions [140]. Evaluating induction of phases I and II metabolism enzymes can also be diagnostic of nuclear receptor activation and provide a means of assessing the relevance of animal findings to humans. While this is often done *in vivo*, hepatocyte models can provide a rapid means of assessing PXR-, CAR-, or AhR-mediated P450 expression in both rodent and human models. This can facilitate an early understanding of potential drug–drug interactions that may contribute to a prioritization of compounds or guide medicinal chemistry to avoid such off-target effects. In rodents, this may also provide an early indication of the potential of a compound to induce liver weight elevation [141]. While hepatomegaly secondary to P450 enzyme induction is often not considered adverse, it may give rise to liver tumors under chronic dosing conditions.

Cell-based models continue to improve and may ultimately provide an accurate portrait of *in vivo* gene expression and function. It is envisioned that the utility of gene expression profiling in these models should further advance our understanding and prediction of drug-induced toxicity. While extrahepatic metabolism, protein binding, and other *in vivo* pharmacokinetic considerations may modify the response in animals, the *in vitro* models should provide a means to study mechanisms of toxicity and identify potential *in vivo* hazards. However, the current use of *in vitro* toxicogenomics to predict *in vivo* responses has not been adequately demonstrated to replace or supplement the use of short-term *in vivo* models in the early evaluation of drug candidates. Hopefully, advances in cell models, such as the use of three-dimensional culture systems or coculture systems, may improve the translatability of *in vitro* gene expression measurements [129].

9.1 INTRODUCTION

Metabonomics, also known as *metabolomics* or *metabolic profiling*, is defined as the measurement of low molecular weight (typically <1500 Da) metabolites and their intermediates in unicellular to multicellular biological systems that reflect the dynamic response to stimuli such as diet, lifestyle, environment, genetic effects, and exogenous factors [1]. The ability to monitor and interpret the multiparametric changes that an organism will experience is of great diagnostic and prognostic value to better understand the metabolic status of the organism and its relationship with induced stimuli. While metabonomics is often referred to studies of the endogenous metabolites, this term has been extended to the environmental chemicals and drugs to which we are exposed [2,3]. Like other “-omics” sciences, which target systems biology at a global level, metabonomics is closely related to complement genomics, transcriptomics, and proteomics [4–7]. In addition, the term *metabolome* has been coined to represent the entire metabolite collection within an organism and is analogous to the genome, transcriptome, and proteome terms already in common use [8].

At the cellular level, exogenous challenges such as drugs, dietary changes, and environmental chemicals can provoke a sequence of biochemical reactions involving receptor activation, gene transcription, and translation to protein products [6–9]. The myriad of cellular biochemical interactions generates a vast and complex array of metabolites. The fact that metabonomics measures the “downstream products” of multiple genes, proteins, and environmental interactions make it a particularly good and reliable reporter of an organism’s phenotype or physiology [10]. This is partially

due to the very different timescales required for the course changes in other “-omics” approaches. For example, gene switching can be very rapid, whereas protein synthesis is typically measured in days or weeks. Pharmacological and toxicological events at the metabolic levels can induce subsequent adaptation and/or feedback effects at the proteomic or transcriptomic levels. Therefore, metabonomics measurements can potentially maximize the probability of capturing meaningful and relevant biochemical changes, and yield important physiological information that is not accessible with gene chips, protein gels, or tissue biopsies [10,11]. Additionally, metabonomics offers the advantage of being applicable to samples collected in noninvasive (e.g., urine), or minimally invasive ways (e.g., serum, plasma, and tissue) [12,13]. This makes dynamic measurement easier without increasing patient morbidity or cost in animal lives. For example, the continuous, individual-specific time course of response can be achievable with urine sampling, providing a full profile of the toxic lesion. Meanwhile, the fact that imaging technologies, especially magnetic resonance imaging (MRI), can detect changes at the metabolic level means that tissue biomarkers generated by nuclear magnetic resonance (NMR)-based profiling can potentially be measured noninvasively *in vivo* [14–18].

The field of metabonomics has experienced a period of exponential growth in recent years primarily due to the technological advances [19,20]. With its unique focus on small molecule characterization, metabonomics is now finding widespread use in disease diagnosis, disease monitoring, nutritional science, and other clinical applications. Metabonomics also provide an effective, inexpensive route to addressing critical issues in the fields of drug metabolism, and drug safety assessment, specifically in regard to, metabolic polymorphism screening [21], toxicity screening [22,23], and biomarker identification [24–28]. These efforts, driven by drug discovery needs, are intended to enhance the quality of lead optimization decisions, decrease attrition with better candidate selection, provide safety screening for better selection of back-up compounds, and provide a tool for continuous safety assessment that can be translated from early development to the clinical studies [29]. While some of the applications have yet to become part of routine pharmaceutical or clinical practice, many of them have including the screening and identification of novel biomarkers of renal and hepatic toxicity [30–33]. The intention of this chapter is to focus on the latest advances in the applications of metabonomics to drug metabolism and toxicology. In particular, we demonstrate how metabonomics has been applied to (i) identification of novel metabolites and metabolic pathways; (ii) screening human metabolic polymorphism; (iii) preclinical toxicity screening; (iv) identification of biomarkers; and (v) investigation of mechanisms of toxicity.

9.2 ANALYTICAL PLATFORMS

The analytical challenge of metabonomics is to provide a comprehensive measurement of small molecular metabolites in the biometrics, both qualitatively and quantitatively. The two principal technologies or platforms used to generate metabolic profiles are NMR spectroscopy and mass spectrometry (MS). Both NMR and MS platforms are capable of profiling the full complement of metabolites in a hypothesis-generating (“open”) manner to provide an all-inclusive spectrum that can be mined for further information on targeted components. However, MS is more amenable to be used in a

TABLE 9.1 Comparison of NMR Spectroscopy Versus Mass Spectrometry for Metabonomics Applications

	NMR Spectroscopy	Mass Spectrometry
Maintenance	Easy to maintain	Not as easy
Instrument run time	Fast, 2–3 min per sample	Slow, 20–30 min per sample
Sensitivity	Less sensitive; detection limits of 10^{-5} – $10^{-4}M$	Superb sensitivity; detection limits of $\sim 10^{-12}M$
Reproducibility	Very reproducible	Not as reproducible
Quantitation	Inherently quantitative	Not quantitative; requires metabolite standards
Sample capacity (samples per day)	Runs up to ~ 300 samples per day with flow probes and automation	Less sample capacity due to requirement for separation
Sample preparation requirement	Requires larger (0.5 mL) samples although microprobes can handle as little as $10\mu\text{L}$; compatible with both liquids and solids (e.g., HR-MAS NMR)	Requires much less sample volume ($1\mu\text{L}$); handle only liquids, and not compatible with solids; requires derivatization for GC
Sample recovery	Nondestructive; samples can be fully recovered	Destructive; samples are not recoverable
Sample analysis automation	Option available to be automated with flow probes and robotic handling instrumentation	Mature technology with fully automated GC- or LC-MS settings
Sample separation	No sample separation required	Requires sample separation
Sample coverage	Excellent; detects all classes of organic species, but not for inorganic ions and nonprotonated species	Good; may requires different ionization sources to get full coverage of metabolites
Resolvable metabolites	Yes; requires large body of software and database for metabolite identification	Yes; excellent for structural elucidation with high resolution MS
Identification of unknowns	Yes; allows identification of novel metabolites	Mature technology for identification of unknown metabolites
Data processing automation	Robust data processing	Mature data analysis tools; large body of MS databases

hypothesis-driven (“closed”) manner, allowing specific analysis of known biochemical entities and chemical classes such as lipids or amino acids [34–36]. The selection of an “open” or “closed” metabolic profiling platform will largely depend on *a priori* knowledge of the biochemical pathways of the associated investigation. Table 9.1 provides a brief comparison of the two analytical platforms one may find useful when considering their potential for metabonomics analysis. A complete discussion of all the technology platforms, methodological details, specific protocols, and potential pitfalls associated with these technologies is beyond the scope of this chapter. Several reviews on these subjects have been recently published [37–40].

9.2.1 NMR Spectroscopy

NMR spectroscopy is an inherently quantitative and nondestructive technique that provides detailed information for hundreds of compounds in a single measurement [41]. During early development of metabonomics, the majority of work in this field was generated using NMR as the method of choice [42–50]. Relative quantitation of small molecule metabolites by performing NMR is intrinsically accurate and precise as demonstrated by the Consortium on Metabonomic Toxicology (COMET) project [51], but caution should be taken in the areas of high spectral overlaps (e.g., sugar area) [52]. Individual signals are dispersed depending on the chemical environment of the source nuclei; hence, NMR spectra are very information-rich with regard to molecular structure. This also means that sample conditions, such as pH and ionic strength, are critically important and will affect the observed spectra [52]. Recent arrangements have included custom-designed automated liquid handlers to minimize sample variations, and sample insertion systems to standardize timing and preparation [53]. Because pH can have a significant impact on chemical shifts of molecules, an automated pH measurement station integrated with a liquid handler will be a very useful module. Although pH is not the only parameter that affects the spectra, its measurement provides an additional level of quality control, as the subsequent multivariate data analysis (MDA) requires spectra to be acquired in the same physicochemical conditions, particular at the same pH [54].

The ubiquitous presence and abundance of hydrogen in biological samples as well as magnetic sensitivity and favorable isotope distributions make ^1H NMR the obvious choice for generating spectrum profiles. There are other NMR active nuclei to study biological samples including ^{13}C , ^{15}N , and ^{31}P . Phosphorus-31 is 100% abundant and is very useful for studying phospholipids and metabolites involved in energy metabolism (e.g., AMP, ADP, and ATP). Low natural abundance and poor magnetic sensitivity of ^{13}C and ^{15}N can also be, in part, overcome by “inverse” methods of detection that typically generate two (2D) or more dimensional data sets combining information from different nuclei on the same molecule to increase the dispersion of resonance [55,56]. These 2D methodologies fall into two categories: protein–protein and proton–carbon correlation experiments. The most active development area is the $^1\text{H}^{13}\text{C}$ heteronuclear single quantum coherence (HSQC) experiment where carbon is used to spread out and resolve peaks in the second dimension [57–61]. A number of investigators have opted for 2D ^1H – ^1H methodologies such as homonuclear correlation spectroscopy (COSY) [62], total correlation spectroscopy (TOCSY) [63], 2D J-resolved experiments [56,64], and DQF-COSY/IDOSY [65] for better sensitivity and compromised on the limited spectral dispersion of proton.

The primary limitation of NMR spectroscopy is the relatively low sensitivity as compared to MS methods. Detection limitations of NMR spectroscopy are typically $\sim 10^{-5} M$ in biofluids or $\sim 10^{-4} M$ in tissue extracts, compared to $\sim 10^{-12} M$ typically achieved by MS [37,39]. Increasing field strength has resulted in considerable enhancements in sensitivity and resolution. Development of cryogenically cooled probes and capillary probes has provided significant improvements in spectral signal-to-noise ratio, and pushed the limits of detection to nanomolar levels or sample volumes as low as 1.5 mL [39]. This enables metabonomics to be applied to a number of volume or mass limited experiments, such as the use of microdialysates and regular blood sampling from small animals without termination.

The development of high resolution magic angle spinning (HR-MAS) NMR allows intact tissues and cells measured directly with little or no sample preparation, affording spectral resolution comparable to that of biofluid NMR [16,66]. Rapid spinning of the sample at an angle of 54.7° relative to the applied magnetic field serves to reduce the line-broadening effects often observed in nonliquid samples such as tissues [16]. These broadening effects are caused by sample heterogeneity and residual anisotropy that are normally averaged out in solution samples such as biofluids. NMR spectroscopy on a tissue sample obtained using HR-MAS NMR is the same as biofluids NMR, and all common pulse techniques can be applied to studying metabolic changes and performing structural elucidation as well as molecular dynamic studies. Profiles generated via HR-MAS NMR have been used to reveal the effects of toxin treatment on the metabolite composition within different cellular environments either via diffusion and relaxation measurements in intact tissues [67–71] or by comparing NMR profiles from various tissue isolates [72,73]. The ability to localize biochemical changes to a specific tissue, cell type, or organelle provides valuable information with regard to investigation of mechanisms of toxicity and can aid the interpretation of biofluid analysis. While the HR-MAS NMR will not be a high throughput procedure in the near future, it provides an alternative means to validate *in vitro* systems in terms of *in vivo* metabolic responses of a specific target tissue to exogenous challenges [24]. This is particularly important when products of intermediate metabolism dominate the observed changes in biofluids and are difficult, if not possible, to link to any specific target organ [31,74]. Several excellent examples of application of HR-MAS NMR technology integrated with traditional biofluid NMR-based metabonomics have been published [75–81]. It is clear that the use of HR-MAS NMR is synergistic with biofluid NMR with regard to understanding drug metabolism and mechanisms of toxicology.

9.2.2 Mass Spectrometry

MS has been widely used for years in metabolic identification and metabolic profiling in the field of drug metabolism. To date, most of MS-based metabonomics have been used on plant metabonomics [27], however, its application to mammalian studies is rapidly increasing [82–84]. The development of multiple soft ionization sources, namely, electrospray ionization (ESI), atmospheric pressure chemical ionization (APCI), and matrix-assisted laser desorption ionization (MALDI), provides the metabonomics researcher with multiple tools to cover the chemical diversity of the metabolome. Yet, the primary limitation of the MS-based metabonomics is that not all metabolites can be ionized with one particular ionization source. As a result, multiple analyses are often needed to provide a complete coverage of different classes of metabolites. The extent of ionization can also be impaired by ionization suppression parameters, such as high salt content, lipids, and other polar moieties [7], underscoring the need for chromatographic separations to minimize or eliminate suppression effects [34,39].

MS as a means of metabonomics research has one major advantage in comparison with NMR, namely, the vastly greater sensitivity. Detection limitations of MS can typically reach up to $\sim 10^{-12} M$ when operating in a full scan mode [82]. This enables MS-based metabonomics to detect small chemical moieties such as sulfate, amine, and carboxyl groups. In addition, the ability to acquire exact masses of metabolites is critical for molecular formula determination and structure elucidation. Fourier transform mass spectrometry (FTMS) and quadrupole-time-of-flight (QTOF) are two major platforms

capable of delivering accurate and reproducible mass information. For example, FTMS can provide extremely high mass resolution ($R = 500,000 - 1 \times 10^6$) and high mass accuracy (<1 ppm) that allows for mass separation and differentiation of complex mixtures without a prior separation by chromatography [85]. Structure elucidation can be further assisted by increasing the collision energies to produce fragment ions.

In general, a prior separation of the complex mixture sample using chromatography is required for MS-based metabonomics, namely, gas chromatography (GC), liquid chromatography (LC), and more recently, capillary electrophoresis (CE) [39]. The resolution provided by multidimensional separations significantly minimizes the problematic effects of ion suppression and “matrix effects,” while at the same time providing further physicochemical discrimination among metabolites. The recently introduced ultra performance liquid chromatography (UPLC) is a combination of a $1.7\text{ }\mu\text{m}$ reversed-phase separation column and a chromatographic system which operates at $\sim 12,000$ psi. With much improved peak resolution and increased speed and sensitivity, the problem of ion suppression from coeluting peaks is greatly reduced [86–90]. UPLC-MS has been used for metabolite profiling of urines from phenotypically normal mouse strains and a nude mouse strain [91]. Its application in the field of metabonomics is rapidly increasing [92,93]. On the other hand, CE, in all its formats, is a high resolution separation technique that is suitable for the analysis of different groups of compounds: charged, neutral, polar, and hydrophobic. Recently, CE-MS has also been explored in the metabonomics research [94–99]. Metabolites are first separated by CE based on their charge and size, and then selectively detected by MS scans. This method has been used to measure 352 metabolic standards and then employed for the analysis of 1692 metabolites from *Bacillus subtilis* extracts, revealing changes in metabolic levels during the bacterial growth [100].

Direct and physical combination of multiple analytical technologies gives the opportunity to obtain structural information from different sources in parallel, and to offer the most comprehensive view of metabolic composition [101,102]. It has already been noted that NMR and LC-MS analysis of the same biological samples from toxicology studies have shown a similar time course of biological events, even if the compared biomarkers are quite different [103]. The most general of the “hyphenated” approaches is the LC-NMR-MS [104], in which the eluting LC peak is split, with parallel analysis by directly coupled NMR and MS techniques. This integrated system can be operated in on-flow, stopped-flow, and loop-storage modes, providing the full array of NMR- and MS-based metabonomics tools [104]. These include 2D NMR spectroscopy, FTMS, or QTOF accurate mass measurement, as well as MS/MS fragmentation for full molecular characterization. Clearly, NMR- and MS-based platforms are highly complementary in the metabonomics field.

9.2.3 Data Processing

Both NMR- and MS-based techniques described above generate large amounts of data per sample, making it impossible to manually organize, analyze, and interpret the multi-dimensional datasets. Chemometrics support is as important as the analytical techniques in the metabonomics research. A number of accessible and useful databases to aid in the identification of unknown metabolites have been listed in Table 9.2. In general, appropriate data preprocessing is required for MDA [105–108]. General procedures include data condensation and reduction, chromatographic (MS) or spectral (NMR)

peak alignment, background filtering, and variable scaling and normalization. To identify principle components (PCs) in a complex dataset, pretreated data are projected onto a new coordinate system based on pattern recognition (PR) algorithm or MDA. There are two categories of MDA methods, namely, unsupervised and supervised MDA, which both have widely been used in metabonomics data analysis [109]. In unsupervised MDA, sample classification is unknown or intentionally blinded to the analysis, while this information is provided to the analytical software in supervised MDA for the purpose of model construction. Both unsupervised and supervised MDA have been used in metabonomics depending on the stage and purpose of the investigation.

Principal component analysis (PCA) has become the most popular unsupervised MDA method that reduces a great number of variables into a smaller number of uncorrelated or independent variables which are called PCs [109]. The first PC explains the greatest variability in the dataset, the second PC is independent of and orthogonal to the first PC and second best explains the variability of the data and so on. In short, PCA is a decomposition of the raw dataset into “scores” that indicate the correlations between the variables. Each point on a metabonomics PCA scores plot represents the whole dataset contained in one spectrum. Thus, PCA plots are very robust for rapid screening of inherent clusters suggesting a comment effect or mechanism, assessment of dose- or time-dependent changes, and identification of individual outliers. Because of its indiscriminate nature, the biomarkers identified in a PCA model can usually be validated. However, the metabolic variations between classes are often very subtle and the inherent complexity of an organism requires utilization of more sophisticated supervised algorithms.

Supervised MDA include partial least squares (PLS), orthogonal partial least squares (OPLS), soft-independent modeling of class analogy (SIMCA), and partial least squares-discriminant analysis (PLS-DA) [109,110]. Supervised statistical methods present the unique advantage of yielding a model that can be readily tested,

validated and ultimately applied for predictive purposes. Indeed, predictability is the main objective for applying metabonomics in the pharmaceutical industry as it can be extremely valuable in identifying novel metabolic pathways, toxicity screening, disease monitoring and diagnoses, and investigation of mechanism of toxicity.

9.3 METABONOMICS IN UNDERSTANDING DRUG METABOLISM

The application of the metabonomics approach in the field of drug metabolism was first introduced in 2003 by Plumb and colleagues [111]. Unlike traditional metabolic profiling with focus on a particular metabolite or group of metabolites, metabonomics measures as many metabolites as possible, both endogenous and exogenous. In the past few years, metabonomics has demonstrated its great potential to accelerate the processes of (i) identifying novel metabolites; (ii) elucidating metabolic pathways; and (iii) identifying human polymorphisms responsible for drug-induced toxicities. Several excellent reviews on these subjects have been published [3,112–114].

9.3.1 Metabolite Identification

Given the low abundance of most drugs and metabolites relative to hundreds of endogenous chemical species present in serum or urine, it is often difficult to unequivocally identify xenobiotic compounds. To date, most of the *in vivo* absorption, distribution, metabolism, and excretion (ADME) studies including drug metabolism studies have been performed using radiolabeled (^{14}C or ^3H) compounds [115]. Radioactivity detection permits not only the identification of drug metabolites, but also the quantitative measurement of absorption, disposition, and routes of excretion. However, the time and costs associated with radiosynthesis, as well as safety and environmental concerns, have largely limited the use of this approach. This has led to a growing shift toward alternative nonradioactive approaches, such as LC-MS and NMR methods [115,116]. In particular, the emergence of high throughput metabonomics approaches has opened up a new vista for the field of drug metabolism [3,117].

One of the recent examples of using the metabonomics approach in metabolite identification was the *in vivo* metabolic profiling of aminoflavone in mice [118]. It was reported that aminoflavone was extensively metabolized to a number of metabolites by CYP1A1 and 1A2 in rat and human microsomes, one of which was a potentially reactive hydroxylamine [119]. CYP1A induction by aminoflavone enhance its own metabolism and toxicity [119]. Given the role of CYP1A isozymes in the metabolism and bioactivation of aminoflavone, a metabonomics study was initiated which employed wild-type, *Cyp1a2*-null, and *CYP1A2*-humanized mice. As a result, 13 metabolites of aminoflavone, of which 12 were novel, were readily detected and identified by using this metabonomics approach with the combination of UPLC-ESI-QTOF-MS and PCA data analysis. In addition, significant difference between wild-type and *Cyp1a2*-null mice, within the relative composition of urinary metabolites, demonstrated that CYP1A2-mediated regioselective oxidation was a major contributor to the metabolism of aminoflavone. Comparison between wild-type and *CYP1A2*-humanized mice further revealed interspecies differences in CYP1A2-mediated catalytic activity [118].

Similarly, 17 urinary metabolites of the potent carcinogen 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine (PhIP), including 9 novel metabolites, were revealed and

Figure 9.1 Identification of novel metabolites and metabolic pathways by the combination of genetically modified animal models and MS-based metabonomics. (a) Experimental scheme. Samples for LC-MS measurement are collected after dosing wild-type, knockout, and transgenic mice with vehicle or xenobiotic. Identification of metabolites and analysis of metabolic pathways are conducted after MDA (supervised or unsupervised) of LC-MS data. (b) Scores plot of a PCA analysis on 24h mouse urine samples from vehicle treatment (Δ , wild-type; $\diamond$, *Cyp1a2*-null; $\square$, *CYP1A2*-humanized) and 10 mg/kg PhIP treatment ($\blacktriangle$, wild-type; $\blacklozenge$, *Cyp1a2*-null; $\blacksquare$, *CYP1A2*-humanized). The $t[1]$, $t[2]$, and $t[3]$ values represent the scores of each sample in principal components 1, 2, and 3, respectively. LC-MS measurement was conducted using UPLC-QTOF-MS (Waters), data processing using MarkerLynx™ (Waters), and MDA using SIMCA-P+ software (Umetrics). (c) Loadings plot of ions in the urine samples from wild-type, *Cyp1a2*-null, and *CYP1A2*-humanized mice treated with vehicle and PhIP. The $p[1]$, $p[2]$, and $p[3]$ values represent the contributing weights of each ion to principal components 1, 2, and 3 of PCA model, respectively. Source: Adapted from Ref. 112.

identified in a single metabonomics study using a high resolution LC-MS system followed by MDA [120]. As depicted in Fig. 9.1, urine samples from the wild-type mice treated with vehicle and PhIP (indicated by arrow points) were clearly clustered and separated in the PCA scores plot (Fig. 9.1b). Accordingly, a metabolic space was created in the PCA loadings plot that defined the PhIP metabolites (Fig. 9.1c). This

study clearly demonstrates that the separation of vehicle-treated and drug-treated sample groups can be conveniently achieved in the scores plot of the multivariate model, and drug metabolites can be subsequently identified by analyzing ions contributing to the separation of drug treatment from vehicle treatment. Structures of these new metabolites were further elucidated by MS² fragmentation analysis [120].

More recently, comparative metabolism of two isomeric oxazaphosphorine cytostatic drugs cyclophosphamide (CP) and ifosfamide (IF) was systemically studied in mice using the MS-based metabonomics [121]. While CP and IF are positional isomers, only IF is known to cause nephrotoxicity and neurotoxicity. The differential metabolism of CP and IF most likely plays a central role in differentiating toxicity profiles of these two isomeric drugs. Thus, a systemic comparison of CP and IF *in vivo* metabolites in mice would potentially reveal reasons for this selective toxicity. Drug metabolites were profiled by performing UPLC-ESI-QTOF-MS and the results were subsequently analyzed by an unsupervised MDA. Of the total 23 drug metabolites identified for both CP and IF, 5 were found as novel metabolites [121]. This study also revealed that IF preferentially underwent N-dechloroethylation leading to the formation of 2-chloroacetaldehyde, while CP underwent ring-opening forming acrolein. In addition, two downstream CP and IF metabolites, namely, *S*-carboxymethylcysteine and thiodiglycolic acid, were produced similarly in CP- and IF-treated mice. These results suggested that other metabolites, perhaps precursors of thiodiglycolic acid, may contribute to IF-induced encephalopathy and nephropathy [121].

A stable isotope-based metabonomics approach has also been developed and applied to facilitate metabolite identification of acetaminophen (APAP) [122]. This is particularly important when the metabolism of xenobiotics dramatically alters or disrupts the endogenous metabolic reactions, and subsequently both xenobiotic metabolites and endogenous ions induced by the xenobiotic treatment contribute to the separation of vehicle and xenobiotic treatment in the PCA loadings plot. By dosing animals with APAP and its stable isotope-labeled form, the contributions of endogenous ions altered by xenobiotics can be phased out using the mass isotopomer analysis and a PCA model. As a result, three novel toxicity-associated APAP metabolites were revealed and identified [122]. These studies, in accordance with recent studies on the metabolism of fenofibrate [123,124], tolcapone [125], arecoline and arecaidine [126], and melatonin [127], underscore the value of MS-based metabonomics approach as a powerful tool for metabolite identification and drug metabolism.

As compared to traditional radioactivity detection methods, metabonomics-based approaches have a clear advantage for not being dependent on the costly and time-consuming preparation of the radiolabeled compounds. More importantly, this systemic approach provides a global view of the detected major and minor drug metabolites in a single metabonomics experiment. Because the existence of xenobiotics and their metabolites in vehicle control and treated samples is a “none-and-all” situation, the variables representing xenobiotic-related species in the multivariate model can be conveniently identified by an unsupervised PCA or a supervised PLS-DA based on their profound contribution to the PCs. As a result, the *in vivo* xenobiotics and their metabolites are screened and identified in a nondiscriminant manner for both common and uncommon metabolic reactions, providing the advantage over the mass defect filtering (MDF) technique that examines the differences of the measured and expected masses of metabolites generated by common biotransformation pathways [128,129].

9.3.2 Elucidation of Metabolic Pathways

Metabolic pathways and the contributions of individual human metabolic enzymes can be evaluated by using recombinant enzymes and specific inhibitors *in vitro*. The major concern associated with these *in vitro* approaches is the lack of physiological context with regard to drug concentration and a complete package of enzyme reaction systems. Genetically modified animal models, such as gene knockout and transgenic mice, provide alternative tools for determining the metabolic pathways *in vivo* [130–134]. Gene knockout models, such as *Cyp1a2*-null mice described above, are ideal for studying the endogenous function of metabolic enzymes and their roles in xenobiotic metabolism. On the other hand, transgenic models, such as *CYP1A2*-humanized mice, are suitable for identifying interspecies difference in xenobiotic metabolism and more importantly can serve as surrogate models for predicting drug metabolism in humans. Because of the systemic and global nature of the “-omics” approaches, the combination of genetically modified animal models and MS-based metabonomics can provide a powerful and efficient technical platform for identifying *in vivo* metabolic pathways.

This integrated approach [120] was applied to determine the role of CYP1A2 and interspecies difference in the metabolism of PhIP. The PCA analysis revealed three distinctive metabolic patterns among the PhIP-treated wild-type, *Cyp1a2*-null, and *CYP1A2*-humanized mice, while the vehicle controls from three mouse lines cluster together in the three-PC scores plot (Fig. 9.1). Subsequent structural elucidation based on accurate mass measurement and tandem MS/MS fragmentation was achieved for these distinctive PhIP metabolites. Taken together, this study demonstrated the role of CYP1A2 in PhIP metabolism and a human–mouse interspecies difference in the catalytic activity of CYP1A2. Mouse CYP1A2 has higher PhIP 4-hydroxylase activity while human CYP1A2 has higher PhIP N2-hydroxylase activity, which is mainly responsible for the genotoxicity of PhIP. In *Cyp1a2*-null mice, PhIP metabolism shifts from the hydroxylation reaction to the N-methylation reaction because of the absence of CYP1A2 enzyme [120]. Additionally, coupled with traditional *in vitro* approaches, this study also demonstrated that other P450s, such as CYP2Cs, are involved in the PhIP metabolism based on the observation that PhIP was still extensively metabolized in *Cyp1a2*-null mice. This finding provides an explanation that disruption of the *CYP1A2* gene in *Cyp1a2*-null mice failed to inhibit PhIP-induced carcinogenesis [120].

More recently, metabolism of melatonin was also evaluated by the combination of genetically modified mouse models and MS-based metabonomics [127]. Metabolite profiling confirmed that 6-hydroxymelatonin glucuronide was the most abundant metabolite in mouse urine. Compared to wild-type and *CYP1A2*-humanized mice, *Cyp1a2*-null mice yielded much less 6-hydroxymelatonin glucuronide (~10%) but more *N*-acetylserotonin glucuronide (~195%), and melatonin glucuronide (~220%) in urine. This study also suggested that there was no apparent interspecies difference between human and mouse with regard to CYP1A2-mediated metabolism of melatonin, but in a significant difference in phase II conjugation, namely, 6-hydroxymelatonin glucuronide in mice and 6-hydroxymelatonin sulfate in human [127].

In summary, these studies demonstrated the combination of genetically modified animal models and MS-based metabonomics as a powerful analytical platform to identify novel metabolic pathways *in vivo*. The graphic presentation of genotype-dependent grouping in the scores plot of MDA models can directly pin down the influence of a targeted gene [xenobiotic metabolizing enzymes (XMEs) or nuclear receptors] on

xenobiotic metabolism [3]. Further structural elucidation of metabolite ions yields important information for the *in vivo* metabolic pathways. On the other front, several XME knockout (CYP1A1, CYP1A2, CYP1B1, CYP2E1, and cytochrome P450 reductase) and humanized (CYP1A1, CYP1A2, CYP1B1, CYP2D6, CYP2E1, and CYP3A4) mouse lines have been established [130–132]. To study drug–drug interactions, knockout and humanized mouse models of nuclear receptors (AhR, PXR, CAR) have also become available [130]. Recently, chimeric mice with liver comprised of more than 80% human hepatocytes have been generated, which holds the promise to simulate human-specific drug metabolism in animal models [135–138]. Coupled with these genetically modified animal models, metabonomics is expected to expand further and find more new applications in the fields of drug metabolism and biochemical pharmacology.

9.3.3 Identifying Human Metabolic Polymorphism

There is a clear case for drug treatments to be selected according to the characteristics of an individual patient, in order to improve efficacy and reduce the number of severity of adverse drug reactions (ADRs) [114]. The occurrence of ADR is not uncommon for many prescription drugs, such as anticancer drugs, but it also occurs for drugs that are widely used, well tolerated, and generally considered as safe [139]. The latter type of ADR has been largely attributed to genetic polymorphisms of drug-metabolizing enzymes. Therefore, obtaining the metabolic information related to ADRs provides a promise to identify the polymorphic changes associated with these patients and in turn, serves as a prediction tools to help establish individualized drug treatment for the susceptible population. One example is the identification of a correlation between CYP2D6 polymorphism [140] and an excessive hypotensive response to debrisoquine [141]. As a result, phenotyping screening of drug candidates with the highly polymorphic P450 enzymes such as CYP2D6 has become a standardized procedure in the pharmaceutical industry to minimize the potential drug–drug interactions in clinical trials. Other examples include the correlation of warfarin responsiveness and genetic polymorphisms in CYP2C9 and VKORC1 [142], and UDP–glucuronosyltransferase 1A1 (UGT1A1) polymorphism and irinotecan [143].

Identification of ADR-related human metabolic polymorphisms still remains empirical and normally engages an extensive investigation of the pharmacokinetics and metabolite profiling of the suspect agent in clinical studies. Because of the multivariate nature and the systemic view into the “downstream products” of multiple genes, proteins, and environmental interactions, metabonomics affords a fresh promise for identifying the genetic polymorphisms associated with ADR, as compared to other “-omics” approaches. For example, over 75 variant alleles of the *CYP2D6* gene have been detected (<http://www.imm.ki.se/CYPalleles/>). Unless every variant site in the genome that affects *CYP2D6* expression is tested, it is extremely difficult, if not impossible, to conclude that a patient is a poor, intermediate, efficient, or ultra-rapid metabolizer based on a DNA test.

In fact, the feasibility of the MS-based metabonomics approach was validated in a proof-of-concept experiment, in which the urine samples from human subjects of known CYP2D6 genotype were analyzed by UPLC-ESI-QTOF-MS and supervised MDA analysis [112]. Samples from poor metabolizers (PMs) were clearly separated from those of extensive metabolizers (EMs) in the scores plot of an OPLS model.

Not surprisingly, the ions contributing most to the separation of PMs from EMs was debrisoquine, while ions responsible for the separation of EMs from PMs are 4-hydroxy-debrisoquine and two ring-open products of debrisoquine [112]. This proof-of-concept experiment clearly demonstrated that the pharmacogenetic phenotypes of CYP2D6 can be visualized and translated to metabolic phenotyping at a systemic level, which provides a rationale for the application of MS-based metabonomics approach to screen human metabolic polymorphisms.

NMR-based metabonomics also showed promise in identifying metabolic polymorphisms. A recent study [21] demonstrated that a combination of pre-dose metabolite profiling and chemometrics methods can predict the outcome for individual subjects. The hypothesis is that “the pre-dose metabolite profile of an individual contains sufficient information to enable the prediction of aspects of drug metabolism and toxicity with any prior knowledge of the subject’s genomic profile.” Major paracetamol-related metabolites included the sulfate, glucuronide, and mercapturic acid, and the nonmetabolized parent drug was also measured. The molar ratio of paracetamol glucuronide to paracetamol (G/P) best predicted the quantities of several post-dose metabolites [21]. A projection-to-latent-structure (PLS) model was constructed and validated to predict the post-dose G/P values for individual rats from pre-dose metabolite profiles. There was a positive correlation ($r = 0.48$) between G/P and the integral of a particular region of pre-dose NMR spectra, and negative correlations ($r = -0.56$ and -0.54) between G/P and integrals of two other NMR regions [21]. Moreover, the principal pre-dose metabolites underlying the mean histology score of liver damage following paracetamol administration included taurine, trimethylamine-*N*-oxide, and betaine. Clearly, these metabonomics approaches have demonstrated its potential in identifying human metabolic polymorphisms, and in turn, hold a great deal of promise to serve as a powerful prediction tool to avoid or minimize ADR in the arena of personalized drug treatment.

9.4 METABONOMICS IN UNDERSTANDING DRUG-INDUCED TOXICITY

One of the earliest applications of metabonomics was the preclinical drug safety assessment and screening of acute toxicity [144]. Metabonomics combines the techniques of high resolution NMR with PR technology to rapidly evaluate the metabolic status of an animal, such that the onset, duration, severity, and target organ localization can be determined from a peripheral sample such as urine. The diagnostic utility of any one trace molecule is limited by the commonality of the biochemical processes disrupted by toxicants due to the number of variables affecting its concentration. However, as metabonomics provides a means to simultaneously target all molecules in the metabolome, the resulting overall pattern as the response to toxic challenges become more consistent and predictive than any single marker. Not surprisingly, many of the available literature on metabonomics and drug development concentrate on its application in drug-induced toxicity and preclinical safety screening [145–149]. To date, the utility of metabonomics in measuring acute preclinical drug toxicity is quite clear. Indeed, with its robust analytical and data processing capacity, metabonomics has been used to rapidly and noninvasively perform a number of toxicological assays including (i) early toxicity screening, (ii) identification of biomarkers to monitor toxicity, (iii) identifying the target organ toxicity, and (iv) investigation of toxicity mechanisms.

9.4.1 Toxicity Screening

Early identification and characterization of a known or presumed toxicity within a pharmacological or chemical class is extremely valuable to drug discovery and development. With its fast NMR spectroscopic acquisition, automated chemometric batch data analysis, and relatively high throughput of sample processing (~300 samples per day) with flow probes and robotic systems, metabonomics provides an efficient tool that uses multivariate PR analysis to effectively perform early toxicity screening [22,23]. In an effort to optimize the process of lead optimization and decrease attrition rates in early drug discovery, metabonomics has been used to define unique spectral profiles that correspond to organ specific toxicities [23].

Toxicity screening using metabonomics is primarily based on the assumption that compounds with similar toxicological profiles will generate similar metabonomics profiles. By building a large spectral database describing hundreds of known toxins with well-characterized pathologies, metabonomics “expert systems” for the prediction of toxicity can be constructed from a series of mathematical models including PCA, neural network analysis, SIMCA, rule induction, and PLS analysis [148]. The statistical models can then be validated with an independent or “test” set of samples, where the outcome of toxicity is known, but not used in the multivariate component analysis. Once validated, the metabonomics “expert systems” can be used to assess and predict the toxicity of drug candidates in the early safety screening. Urine samples appear to be the biofluid of choice for toxicity screening because of the adequate volume available for repeated sampling and its noninvasive nature for collection in refrigerated metabolism cages [150]. Representative ^1H NMR spectra of control rat urine and blood serum samples are shown in Fig. 9.2, displaying a wide range of metabolites such as sugars, amino acids, osmolytes, as well as of larger molecules such as lipoproteins. Other target tissues, such as renal papillary, renal cortex regions (S1 and S3) [151], renal glomerula, testes, and liver [152–154] are also considered suitable for toxicity screening by metabonomics approaches.

While the initial support for the use of metabonomics as a fast and inexpensive solution to laborious toxicological and histopathological screens has cooled recently, metabonomics is still being used as a safety screening approach by pharmaceutical industry [29]. The major hurdle for practical use of metabonomics-based toxicity screening is that the data profiles generated are rarely simple and each toxin induces its characteristic lesions with its own time-dependence, recovery rate, excretion profile, and effects on other tissues. Therefore, assignment of a particular toxicity to an unknown compound, based on spectral profiles, is not always straightforward and reliable. Because the development of robust and reliable paradigms for drug safety screening requires substantial data analysis efforts to transfer the large spectral database into classification systems that are able to distinguish between toxic and nontoxic compounds, a COMET was formed between five major pharmaceutical companies (Bristol-Myers-Squibb, Elli Lilly, Hoffmann-La Roche, Novo Nordisk, and Pfizer) and the Imperial College London, UK [51]. The main objects of COMET were to assess and develop methodologies to generate a metabonomic database using ^1H NMR spectroscopy of rodent urine and blood samples for preclinical toxicity screening of drug candidates, and to build a predictive expert system for target organ toxicity [51]. The chosen COMET target compounds represented a wide range of metabolic space with diverse structures and pharmacological activities, carrying its focus on building a

Figure 9.2 (a) Representative ^1H NMR spectrum of control rat urine displaying a wide range of metabolites such as aromatic, aliphatic compounds, sugars, amino acids, and other osmolytes. (b) Representative ^1H NMR spectrum of control rat blood serum sample showing signals of low molecular weight metabolites as well as of larger molecules such as lipoproteins. LDL, low density lipoprotein; VLDL, very low density lipoprotein. *Source*: Adapted from Ref. 66.

database for predicting kidney and liver toxicity in rat and mouse. A previous subset of the COMET project with 19 model toxins reported a predictability of 86% for the control group, 85% for the hepatotoxicity group, 91% for the nephrotoxicity group, and 88% for the other toxicity group, thereby illustrating the potential value for this application [155]. Recently, the COMET database was also used to develop an expert system for prediction and classification of drug-induced toxicity, which enabled collections of metabolic trajectories representing diverse responses to nephrotoxins and hepatotoxins to be compared, and the likely type of toxicity from a drug candidate to be predicted [156]. A subset of the COMET database representing 80 model toxins was used to build a modeling system that was capable of differentiating NMR urinary metabolic profiles from controls and treated animals. The classification of unknowns by density superposition (CLOUDS) approach [156,157] was then applied to determine similarities between different treatments, which enabled the separation of kidney and liver toxins based on their urinary metabolic profiles, providing the similarity matrix/pattern which could be used to predict the toxic outcomes of unknown treatments. The sensitivity and specificity of this expert system for liver toxins were 67% and 77%, and for kidney toxins, 41% and 100%, whereas the predictability of the system had an error rate of 8%. To date, this approach has provided the largest validation of the application of metabonomics in preclinical safety assessment and offered practical utility for *in vivo* drug toxicity screening in animal models.

To gain knowledge and confidence in the ability to screen and identify drug candidates with potential toxicological liabilities remains as the key for the toxicity screening using metabonomics approaches. Whether a preclinical animal model is indeed representative of how the drug would behave in humans remains to be monitored and validated. Another assumption is that animal models would also provide safety assessment of idiosyncratic responses in humans. Because idiosyncratic toxicity is by definition physiological response peculiar to an individual who does not respond as the majority of population, building a predictive model for idiosyncratic toxicity can be a very challenging venture that requires systemic understanding of underlying mechanisms by which idiosyncratic events may occur, such as genetic variations, genotypic diversity, disease status, environment factors, diet, and relevance to human. An alternative approach to elucidate idiosyncratic toxicity may reside in the use of metabonomics platforms to analyze the biofluid samples from individuals subject to idiosyncratic responses in a well-targeted clinical protocol [114].

9.4.2 Biomarker Identification

The quest for biomarkers in the pharmaceutical industry is imminent, and any biomarker that can either exclude patient *a priori* [21] or enable early removal of patients before significant adverse effects occur is highly desirable. As summarized in Table 9.3, metabonomics has demonstrated, to date, its enormous potential to identify novel biomarkers of drug-induced toxicity, with early work focused primarily on biomarkers of renal and hepatic toxicity [158–171]. Having established that a given compound reproducibly alters the metabolic profile of an organism, the metabolites that differentiate between biofluid samples from control and treated animal models can be elucidated. One of the examples for hepatotoxicity biomarkers was metabonomic detection of drug-induced phospholipidosis [167,168]. As an early onset of hepatotoxicity, drug-induced phospholipidosis is often difficult to be detected

TABLE 9.3 Summary of Biomarkers Determined by Metabonomics

Species	Metabonomics Biomarkers	Associated Toxicity
Rat	↑ Phenylacetyl glycine (PAG) and dimethyl glycine (DMG)	Phospholipidosis, liver necrosis
Rat	↑ Urinary taurine and creatine; bile aciduria	Liver lesions/cholestatic lesions
Rat	Urinary dicarboxylic aciduria; ↑ taurine and ↓ citrate, succinate, 2-oxoglutarate, and hippurate	Impaired fatty acid metabolism/liver toxicity
Rat	↑ Urinary taurine and creatine	Liver lesions
Rat	↑ Serum creatine	Liver (hepatocellular necrosis, steatosis, cholestasis)/testicular lesions
Rat	Altered serum/plasma lipoproteins (changes in broad alkyl features)	Liver toxicity
Rat	↑ <i>N</i> -methyl nicotinamide (NMN) and <i>N</i> -methyl-4-pyridone-3-carboxamide (4PY)	Peroxisome proliferation
Rat	↑ Urinary trimethylamine <i>N</i> -oxide (TMAO), trimethyl amine (TMA), dimethyl amine (DMA), betaine; ↓ DMG, citrate, β-hydroxy butyrate, α-ketoglutarate (ketone bodies)	Renal papillary necrosis
Rat	TMAO perturbation, ↑ DMG, DMA, and succinate	Renal papillary lesions
Rat	↑ Glucose, various amino acids; ↑ organic acids or lactate, ↓ citrate, succinate	Renal proximal tubule
Rat	Early ↑ urinary polyamines, sugars (glucose, mannose, fucose, <i>N</i> -acetylneuraminate, and gluconate); amino aciduria; ↑ urinary phosphate, 3-hydroxybutyrate, 3-hydroxyphenylacetate, monoethanolamine, and hippurate	Early kidney malfunction, nephrotoxicity
Rat	↑ Glucose, acetate, TMA, succinate; ↓ TMAO, kynuric acid, xanthurenic acid, citric acid, riboflavin	Cyclosporine A-induced nephrotoxicity
Pig	↑ Urinary TMAO, DMA, acetate	Renal medullar damage by ischemic reperfusion injury
Rat	Ketone bodies in plasma: 3-hydroxybutyrate, acetoacetate.	Fasting/reduced feeding/ketosis
Rat	↓ Alanine and lactate concomitant with ketone bodies in plasma	Gluconeogenesis
Human	Urinary salicylic acid (~75%), salicyluric acid (~20%), and gentisic acid (~5%)	Lysine acetylsalicylate poisoning
Human	Appearance of urinary valproyl- <i>O</i> -glucuronide	Valproic acid poisoning
Human	Appearance of urinary paraquat (dimethyl-bipyridylium ion)	Paraquat poisoning
Human	Appearance of tetrahydrofuran (THF) and 4-hydroxybutyric acid, and lactate in urine and plasma	THF poisoning
Human	Urinary ethylene glycol and glycolic acid	Ethylene glycol poisoning

by conventional biochemical procedures, such as histopathology. By using NMR spectroscopy and PR methods, the authors have shown that administration of two cationic amphiphilic drugs (CADs) induced foamy alveolar macrophages in rats, and resulted in urinary increase of phenylacetylglycine (PAG) with decreases in citrate and 2-oxoglutarate. The mechanism by which PAG is elevated as result of phospholipidosis is unclear. The association of increased urinary PAG levels in the event of phospholipidosis was later confirmed for three other CADs administered in rats, namely, amiodarone, chloroquine, and DMP 777. This study demonstrated that monitoring PAG in rat urine as a biomarker of phospholipidosis is a promising development [167–169].

Recently, metabonomics has also revealed two novel biomarkers for peroxisome proliferation (PP) in Wistar Han rats, namely, *N*-methylnicotinamide (NMN) and *N*-methyl-4-pyridone-3-carboxamide (4PY) [159]. Because many lipid-lowering drugs can induce PP, early biomarkers that detect PP in animal models have been pursued [159]. Although there is little evidence of significant PP in human, the assessment of human hepatic responses to drugs such as PPAR α agonists is hampered by the lack of PP biomarkers, as well as the limited understanding of the mechanisms of PP in rodents. Both NMN and 4PY are end products of the tryptophan-nicotinamide adenine dinucleotide (NAD⁺) pathway. Urinary NMN and 4PY were elevated 24- and 3-fold, respectively, with a correlation between NMN and peroxisome count of $r = 0.87$ ($r^2 = 0.76$) [159]. The metabonomics datasets were further exploited to build a PLS predictive model for PP and successfully applied to classify samples from Sprague-Dawley rats dosed with fenofibrate, a PP model drug [160].

There are also novel hepatotoxicity biomarkers identified by MS-based metabonomics approaches. It was reported that GC-MS was used to study carbon tetrachloride (CCl₄)-induced acute liver injury in mice [172]. A systemic metabolic profiling of liver tissues and plasma at various post-dose time points was completed, and the study showed elevated levels of malate and several fatty acids in the liver, as well as increased concentrations of citrate and several amino acids. The relative levels of several bile acids have been reported as better indicators of liver functional status than total bile acids. Recently, a UPLC-MS-based metabonomics method was used to investigate bile acid changes in rodent models of liver failure induced by CCl₄ and α -naphthylisothiocyanate (ANIT) [173]. Twenty-two bile acids were evaluated in the rat serum by PCA along with canonical discriminant analysis, and the results demonstrated that levels of the different bile acids varied between treated and untreated rats and the pattern could potentially serve as a more sensitive indicator of hepatotoxicity.

Recently, an increased number of metabonomics studies have employed both NMR and MS to provide a more complete understanding of the metabolic changes in response to toxic challenges, particularly in the search for the new biomarkers of nephrotoxicity [174,175]. Gentamicin is an aminoglycoside antibiotic prescribed to treat life-threatening infections but causes a 10–15% incidence of nephrotoxicity. A combined NMR and HPLC-TOF-MS study of gentamicin-induced nephrotoxicity in rats detected an increased urinary level of glucose and decreased level of trimethylamine N-oxide (TMAO) by NMR with decreases in xanthurenic and kynurenic acids and changes in sulfation patterns by MS [176]. Glucosuria has been previously shown as a potential marker of nephrotoxicity [176,177]. In a separate study that investigated the effect of age on the severity of gentamicin-induced renal toxicity in Sprague-Dawley rats, UPLC-ESI MS showed increases in urinary levels of 6-hydroxymelatonin that

directly correlated with the histopathology findings [178]. 6-Hydroxymelatonin is an oxidized by-product of melatonin, a powerful antioxidant that has been demonstrated to act as a scavenger of nitric oxide [179]. Melatonin supplementation in Sprague-Dawley rats has also been shown to protect the kidney from gentamicin and mercuric chloride induced renal toxicities [180,181]. Therefore, the elevated urinary levels of 6-hydroxymelatonin may represent the increase in melatonin as the body tries to protect against kidney damage following dosing with gentamicin. Taken together, these studies demonstrated great potentials of the combination of both MS- and NMR-based metabonomics approaches in identifying novel biomarkers, as well as elucidating the mechanism of toxicity.

9.4.3 Mechanisms of Toxicity

While mechanisms of toxicity and biomarkers are closely linked together as described above, a mechanistically elucidated biomarker should be far more predictive and therefore valuable. Metabonomics has proven to be a powerful tool for gaining insights on the mechanism of drug-induced toxicity. Most of the mechanistic metabonomics work has been focused on nephro- and hepatotoxicity, linking the temporal metabolic dysregulation with toxicity endpoints [24,31,74].

Several samples of metabonomic investigations of the mechanisms of drug-induced toxicity have been published. The neurotoxic effects of hydrazine was mechanistically linked to the markedly elevated levels of 2-aminoadipate (2AA), which is known to affect kynurenic acid levels in the brain. The results provided a plausible hypothesis for the heretofore unexplained neurotoxicity of the compound [182]. Clayton *et al.* mechanistically linked creatine to hepatotoxicity via effects on cysteine synthesis, and later on the elevated creatine levels were related with hepatotoxicity and nutritional effects [162,183]. Urinary dicarboxylic aciduria has also been associated with impaired fatty acid metabolism, which may be common to hepatotoxicity [183].

Whereas investigation of toxicity mechanisms is an ongoing subject, novel integrated metabonomics studies have also served to enhance the utility of the technology for mechanistic purposes, notably the HR-MAS NMR for metabolic profiling of intact tissues (Section 9.2.1). These efforts have been successfully employed to study the mechanisms of toxicity of acetaminophen [81], ANIT [79], Bay41-4109 (an anti-HBV compound) [184], and cadmium [185].

9.5 CONCLUSIONS AND FUTURE PERSPECTIVES

This chapter has attempted to highlight some of the key applications of metabonomics in drug discovery and development. While MS-based platforms have demonstrated clear advantage in identifying novel metabolites and metabolic pathways in the drug metabolism field, biofluid and tissue NMR play a growing role in the drug safety screening and biomarker identification. Both MS- and NMR-based platforms have shown great values toward a deeper understanding of drug metabolism and drug-induced toxicity, and an integrated approach will provide a holistic metabolic profile of biometrics. Although each technology is currently evolving in its full speed, future

developments, such as construction of merged databases of metabolome and their associated metabolic pathways containing both MS- and NMR-derived information, will greatly facilitate the identification of thousands of metabolites and metabolic networks.

Owing to its nature measuring the “downstream products” of multiple genes, proteins and environmental interactions, metabonomics best reflects a phenotypic metabolic status and therefore has great potentials to generate valuable data for a “systems biology” approach. In the studies of drug metabolism and toxicology, however, the integrated approach applying all the accessible technologies (e.g., genomics, transcriptomics, proteomics) will have the best chance of success, simply because biochemical interpretation of results from each of these “-omics” approach individually can lead to premature conclusions as exogenous challenges can perturb cellular processes at multiple molecular levels [54]. Meantime, to achieve the objective of understanding the mechanisms of drug metabolism and toxicity-related events, careful experiment design, well-controlled sample collection, high resolution data acquisition, robust data processing, and stringent data analysis are critically important and remain to be further improved.

It is clear that metabonomics will continue play an increasing role in the fields of drug metabolism and drug safety evaluation. It can also be expected that metabonomics will enter the “mainstream” activities of pharmaceutical research in the foreseeable future. As a result, successful impact of metabonomics on the pharmaceutical portfolio should lead to a reduction in the attrition rate of drug candidates in the pharmaceutical R&D process, and in turn, determine future investment, support, and sponsorship for this rapidly evolving field.

10.1 SUMMARY

Aided by major technological advances, the field of proteomics has become extremely active in the identification of drug targets that can guide drug development and treatment decisions and ultimately improve treatment outcomes. Proteomics has provided a means for molecular profiling that will assist in the development of tailored therapies. Although the implementation of genomic and proteomic testing in clinical practice is still in its infancy, the rapid development of new technologies and platforms provides hope for personalized medicine. This chapter describes these technologies and platforms, presenting many of their technical aspects along with examples of how they have been implemented in pharmaceutical applications.

10.2 INTRODUCTION

Target identification, lead identification, small-molecule or therapeutic protein drug optimization, and preclinical and clinical development are four major phases involved

in drug discovery. Advanced genomic, proteomic, and metabolomic technologies have been applied to one of the key steps in drug discovery, target identification, primarily because of their high throughput and large-scale analysis capabilities. However, many genomic study results have shown poor correlation with protein expression or mutation data. Moreover, genomic analysis lacks the ability to detect and characterize protein posttranslational modifications (PTMs). The measurement of genomic profile has proven to be inadequate in drug target identification. In recent years, global analysis of gene expression at the protein level and protein PTM analysis have taken the center stage in studying protein expression profiles and alterations under defined biological conditions. Proteomic technologies are growing at an extremely rapid rate and have revolutionized the way in which biological research is conducted. These technology-driving methods will no doubt be very valuable for diagnostics, prognostics, therapeutics, and drug discovery, leading to improved human health.

10.2.1 Proteomics Platforms

Proteomic analysis is most commonly accomplished by a combination of either two-dimensional gel electrophoresis (2DE) or liquid chromatography (LC) to separate and visualize proteins/peptides and mass spectrometry (MS) to identify, characterize, and quantify them.

The power of 2DE in proteomics lies in its ability to enable parallel processing of hundreds (or even thousands in many cases) of proteins concurrently. Although this technique is powerful, reliable, and effective, its lack of ability to characterize all the elements of a proteome is still its biggest disadvantage. 2DE fails in three areas: (i) the ability to detect and analyze low abundant proteins; (ii) the ability to separate proteins at the extremes of isoelectric point (pI), molecular weight (MW), and hydrophobicity; and (iii) the ability to analyze proteomes in a high throughput fashion. The individual extraction, digestion, and analysis of each spot from a 2DE gel are tedious and time-consuming processes that limit its ability to be a high throughput method.

One logical way to improve the 2DE technique is to prefractionate the protein samples to enrich for the less abundant proteins. Alternatively, nongel-based chromatography systems, such as the LC-MS-based shotgun proteomic method, can provide a powerful tool to resolve and identify thousands of proteins from a biological sample. In this method, proteins are first digested by a protease into a peptide mixture, which is then analyzed by LC/MS/MS and subsequently identified by database searching. This approach is rapid and more sensitive. It can be automated and has the ability for large-scale proteome analysis, but it requires significant bioinformatic resources for data analysis, and relative quantification remains very challenging without isotopic labeling.

Although these current technologies can facilitate diagnosis and drug development, they are still far from perfect. The barriers that hinder accurate and robust analysis of samples include (i) the protein dynamic range ($>10^9$), which poses a daunting analytical challenge for less abundant proteins; (ii) protein quantification; (iii) the identification of PTMs and splice variants, which remains sophisticated and time consuming; and (iv) the lack of high throughput and reproducible validation strategies for protein identification and quantification.

10.3 2DE-BASED PROTEIN EXPRESSION ANALYSIS

Despite its limitations [1], a principle core technology of protein separation and analysis still lies in the 2DE separation of the complex mixture of thousands of proteins represented in a living cell. Rather than an emerging technology, 2DE is an approach with a 36-year history. The analysis of protein expression profiles using a 2DE approach, combining separation by isoelectric focusing and denaturing by sodium dodecyl sulfate (SDS) electrophoresis, was first published in 1975 independently by Klose and Spielmann [2], O'Farrell [3], and Scheele [4]. Global protein analysis using 2DE was proposed early the next decade [5,6] and technical improvements, making it a large-scale, quantitative, and qualitative analytical tool, have continued to the present [7]. In conjunction with 2DE, enzymatic cleavage of separated proteins, tandem mass spectrometric (MS/MS) analysis of the resulting peptides, and online peptide sequence database searching for protein identification comprise a typical "gel-based proteomics" platform.

10.3.1 Principles of the 2DE-Based Approach

10.3.1.1 Two-Dimensional Electrophoresis. 2DE protein separation typically resolves 1000–2000 proteins in a single tissue sample and up to 10,000 on a large format gel [8], even when moderately sensitive stains are used. Saturation labeling of proteins with fluorescent cyanine (Cy) dyes provides even greater sensitivity, particularly when samples are very small [9]. Proteins are separated based on their charge, a function of their constituent acidic and basic amino acids and chemical modifications therein, by isoelectric focusing (IEF) in the first dimension and then by molecular mass via sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE or DALI) in the second dimension. When combined in this manner, these two separation techniques produce a unique two-dimensional protein pattern representative of the molecular phenotype of the subcellular organelle, cell, or tissue. A typical 2DE protein pattern obtained from a rodent liver sample is shown in Fig. 10.1. This pattern contains nearly 3000 features (300 alone in the boxed region), providing an excellent snapshot of the most abundant portion of the hepatic proteome. The 2DE protein pattern can then be subjected to image analysis where each protein spot is assigned an x and y coordinate position, and the spots in each pattern are matched to a standard master or reference pattern. Quantification based on protein spot optical density and alterations in abundance, charge, and/or molecular mass can then be determined relative to a standard pattern using statistical analysis tools. Changes in abundance suggest upregulation or downregulation of gene expression or altered protein turnover rates. Modifications in charge and/or molecular mass indicate posttranslational protein modifications, such as phosphorylation, glycosylation, prenylation, cleavage, or genetic polymorphisms. Of particular relevance to the pharmacologist are the detectable charge modifications associated with conjugation, chemical adduct formation resulting from interactions with reactive intermediates resulting from drug metabolism, or amino acid substitutions resulting from point mutations in the genome. A brief summary of the individual components of the 2DE approach is presented below, and the overall scheme is depicted in Fig. 10.2.

Figure 10.1 Large-format 2DE gel ($20 \times 25 \times 0.15$ cm; stained with colloidal CBB) image of whole rat liver lysate. The coordinate pattern reflects a pH gradient (IPG) of roughly 3–10 and a mass range from ~ 10 –200 kDa (bottom to top). Over 2000 protein spots are detectable in the entire pattern, and the boxed area (~ 2 pH units $\times$ 30 kDa) contains over 300 features.

Figure 10.2 Standard platform and analytical work-flow for 2DE, including protein identification by LC/MS/MS. TPP, Trans proteomic pipeline.

10.3.1.2 Sample Preparation. In the analysis of differential protein expression resulting from toxic exposure, optimal sample solubilization is critical, and unnecessary sample handling and artifactual alteration of the isolated proteins must be avoided. Generally, one should use a one-step solubilization technique that involves physical disruption of tissues, cells, and organelles via ground-glass or Teflon homogenization, or ultrasonication in a single medium. This enables the simultaneous solubilization, denaturation, and reduction of sample proteins, breaking noncovalent and disulfide linkages, removing interfering substances such as nucleic acids, and inhibiting the actions of intracellular proteases [10]. Prepared in this way, proteins can be separated as the monomers encoded by the genome while the covalent PTMs that typify certain proteins and cellular conditions remain unaltered. A typical solubilization medium contains 7–9 M urea, 4% nonionic or zwitterionic detergent such as 3-[(3-cholamidopropyl) dimethylammonio]-1-propanesulfate (CHAPS) or Igepal CA-630 ([octylphenoxy] polyethoxyethanol), and 50–100 mM dithiothreitol (DTT) or tributylphosphine as a reducing agent. When immobilized pH gradient (IPG) strips are used for first-dimension separation, protein hydrophobicity becomes a problem. In this case, combining urea and thiourea in a two- to fourfold ratio during solubilization and IPG strip reswelling prevents protein adsorption to the IPG strip and loss of resolvable proteins [11].

10.3.1.3 First-Dimension Isoelectric Focusing. After solubilization (and prefractionation if desired), protein samples are separated according to their charge by IPG electrophoresis on gel strips. IPG strips consist of IPGs [12] with pI resolution up to 0.01 pH unit attainable in highly stable gradients where cathodic drift is minimal. Because each IPG strip is cast with a rigid backing, it has improved physical stability over tube gels, which simplifies handling and avoids gel breakage. Gel sample loading is simple and takes advantage of the commercially available IPG strip shipped in the dehydrated form. By uniformly rehydrating (reswelling) the entire length of the dried IPG strip with sample-containing buffer, problematic sample precipitation at a single application point is avoided, control of quantitative sample loading is improved, and, if necessary, >10 mg protein can be loaded to improve detection of low abundance proteins. Broad pH ranges and alkaline stability have produced IPG strips with functional immobilized gradients of pH 3–12.35, although narrow-range pH gradient strips are also available for analyzing proteins within a specific pI range.

10.3.1.4 Second-Dimension SDS-PAGE. After first-dimension IEF, the gel or strip is placed on a polyacrylamide gel slab for separation by molecular mass, producing a 2D pattern. The procedures involved in SDS slab gel electrophoresis vary according to the apparatus available, with most 2D systems limited to 2–12 slab gels per run. Some large-scale systems support 20 gels per run and these are particularly useful in studies where the effects of several dose groups on protein expression are being compared. A highly parallel slab gel system significantly reduces gel to gel variability and improves gel imaging and quantitative/qualitative protein analysis. SDS is an anionic detergent that denatures proteins and forms anionic complexes with constant net negative charge/mass ratio. Proteins treated with both SDS and a reducing agent, such as DTT, can be separated exclusively by MW (mass/charge). Most 2DE platforms use a tris-glycine buffer system similar to that originally described by Laemmli [13]. On the basis of its sieving properties, polyacrylamide significantly

affects protein mobility particularly when one alters acrylamide concentrations. Incorporation of acrylamide gradients optimizes resolution of heterogeneous mixtures of low, high, and intermediate MW proteins typically found in target tissues such as liver, kidney.

10.3.1.5 Protein Detection and Quantification Methods. Vital to an effective proteomics platform is the ability to quantitatively detect the resolved protein pattern in a manner that is both accurate and reproducible. A number of different methods can be used to stain and detect proteins separated by 2DE and all have their own unique limitations. The most critical properties of protein detection methods used in gel-based proteomics include high sensitivity (and a concomitant low detection limit), wide linear dynamic range (for accuracy), reproducibility, cost-efficiency, ease of use, and, perhaps most importantly, compatibility with subsequent MS protein identification and characterization techniques. Unfortunately, no single detection method meets all these requirements.

One method that is more effective than the classical “staining techniques,” in terms of sensitivity, dynamic range, and reproducibility, is the use of radiolabeled proteins (by *in vivo* metabolic incorporation of radioactive amino acids such as ^{35}S -methionine or ^{14}C -leucine into proteins), along with autoradiography and image analysis. However, the use of radiolabeled compounds is frequently impractical, particularly in routine, high capacity applications.

10.3.1.6 Protein Detection. Historically, one of the first dyes with widespread use for polyacrylamide gel-based protein staining was Coomassie brilliant blue (CBB) R-250 because its staining intensity is relatively linear (10- to 30-fold) over an acceptable range of protein concentration [14] and is thus excellent for densitometric protein quantification. CBB-stained proteins are particularly useful for proteomic studies because they are fully compatible with all forms of MS analyses of their tryptic digests. However, CBB R-250 is rather insensitive ($\sim 100 \text{ ng/mm}^2$) so that low abundance proteins are left largely undetected. By using a colloidal CBB G-250 staining protocol [15], protein detection can be greatly improved, as it approaches the sensitivity of some silver stains at $\sim 1 \text{ ng/mm}^2$. In addition, to overcome CBB R-250's lack of sensitivity, protein electrophoretic silver stains were perfected [16]. Ammoniacal (alkaline) silver staining can be very sensitive (0.1 ng/mm^2) but only has a ~ 10 -fold dynamic range. Furthermore, MS of tryptic digests from silver-stained proteins tends to be problematic [17], requiring an additional step of silver removal (destaining) with potential protein loss. Furthermore, slight variations in the reagents often caused major differences in staining intensity and background, thus creating quantification problems in large-scale experiments with very large numbers of gels.

Of significant impact was the development and 2DE application of fluorescent stains, such as the ruthenium-based SYPRO Ruby protein gel stain [18,19] with a $1\text{--}2 \text{ ng/mm}^2$ sensitivity and a dynamic range of nearly three to four orders of magnitude and Flamingo, an even more sensitive fluorescent dye [20], and the use of Cy dyes (Section 10.3.2.1) have had an even greater impact on detection sensitivity and reproducibility. Despite the great advances in sensitivity and dynamic range, the identification of proteins in gels stained in this manner is difficult and often requires a replicate gel that has been loaded with sufficient protein (overloaded in comparison to the Cy-labeled sample) and can be CBB-stained to obtain a plug for proteolytic

digestion that contains enough protein for MS detection of an accurate m/z measurement, especially in matrix-assisted laser/desorption ionization mass spectrometry (MALDI-MS) applications.

Given the interest in protein PTM status and its profound effect on biological activity, in lieu of actual gene upregulation and downregulation, numerous stains have been developed to detect prominent protein modifications such as glycosylation and phosphorylation. In 2001, a sensitive (1 ng/mm^2) green-fluorescent periodate Schiff-base, glycoprotein-specific stain referred to as *Pro-Q Emerald dye* was developed [21], which allows detection of glycoproteins directly in polyacrylamide gels or on polyvinylidene fluoride (PVDF) membranes. Similarly, Pro-Q Diamond is another fluorescent stain [22] capable of sensitive detection of phosphorylated amino acid residues in proteins separated in 1D and 2D gels, which has a sensitivity similar to the Pro-Q Emerald dye. Sequential staining and multiplexing with all three fluorescent stains is possible [22–24] and can be combined with Cy dye technology [25].

10.3.1.7 Image Analysis. Successful application of 2DE in pharmacology relies on accurate protein differential expression analysis. This necessitates precise comparison of individual protein abundances in control versus sets of treated groups to properly describe the dynamics of the experimental conditions and to distinguish the magnitude and statistical significance of various biological effects. Therefore, optimized protein separation, detection, quantification, and identification methods are central to this application and to proteomics in general [26]. There is currently no practical approach to routinely and precisely measure the absolute amounts of each protein present in a typical 2D gel. However, one can accurately quantify protein abundances relative to a reference pattern. Nevertheless, gel imaging systems are commercially available for any manner of protein stain or detection methodologies. As a result, relative protein abundance can be determined and quantitative differences in protein expression statistically compared using these analysis systems.

Most 2D gel image analysis packages commonly consist of (i) scanning a stained 2DE pattern via laser densitometry, photodiode array, or fluorescence emission detector; (ii) digitizing the image; (iii) processing the image (e.g., background and streak subtraction and mathematical morphology operations to detect and optimize each spot); and (iv) creating a reference pattern to which all other patterns are then matched to create a set of essentially superimposable 2D protein patterns. Lists of matched protein spot abundances can then be subjected to statistical analysis to search for quantitative, qualitative, and positional (charge) alterations in the proteome patterns. Despite nearly three decades of 2D gel image analysis research and development, the various strategies employed by the numerous software platforms continue to account for at least part of the variability associated with gel-based proteomics [27–29], and great care must be taken when employing this aspect of the 2D gel-based approach.

10.3.1.8 Protein Identification. After 2DE separation and image analysis, any or all the proteins in the gel pattern can be selected for identification. In large proteomic projects, the ultimate goal is to identify all expressed proteins [30]. In less ambitious, more focused studies, only those proteins altered in response to some experimental manipulation/disease state or those detected in greatest abundance are selected for identification. Regardless of project scope, protein identification is becoming less problematic as a result of technical developments in both traditional approaches that are

slow and labor intensive and contemporary techniques that are fast, less expensive, and appropriate for high throughput applications.

10.3.1.8.1 Immunoblotting. The most traditional method of protein identification involves Western blotting and immunostaining [31]. Proteins on 2DE gels are transferred electrophoretically onto a suitable membrane (e.g., nylon, nitrocellulose or PVDF), and the membrane is probed with a primary antibody that binds to the desired membrane-bound protein. If the desired protein is present, it is detected by the application of a secondary antibody incorporating either a radiolabeled molecule or an enzyme that yields a colored product on addition of an appropriate substrate. Although this approach can be extremely precise, it is labor intensive and requires significant optimization for each protein. Furthermore, nonspecific binding of either primary or secondary antibodies can be misleading. Because immunoblotting searches for known proteins with available antibodies, it is not appropriate for global protein identification. The technique's greatest utility may relate to the selective use of antibodies whose epitopes recognize posttranslationally modified proteins such as phosphoproteins [32,33] or other covalent adducts [34–36] to characterize epigenetic phenomena.

10.3.1.8.2 Mass Spectrometric Peptide Mass Fingerprinting. With vast electronic protein sequence databases containing an ever increasing fraction of the proteins coded by organismal genomes, and MS techniques that now enable the routine analysis of proteins and peptides with extremely high sensitivity and excellent precision, high throughput protein identification via peptide mass fingerprinting (PMF) is quite practical. This approach has been reviewed thoroughly [37] and is described briefly in this section. Essentially, proteins separated on a 2D gel are cut from the gels, proteolytically cleaved into their constituent peptides, the peptide ions are detected by MS, and the resulting masses are compared to theoretically derived databases of peptide masses generated by calculating all possible mass fragments (using a variety of fragmentation techniques) for all known protein sequences. Although several different approaches to generating measurable peptides are possible, the enzymatic in-gel digestion of proteins using a suitable protease such as trypsin is most common. Trypsin is an endopeptidase that cleaves peptide bonds at the C-terminal side of lysine (K) or arginine (R) residues. This protease, along with Lys-C, has been the preferred enzyme for proteomic applications mainly because it generates peptides in the 800–2500 kDa range, optimal for contemporary MS techniques. Nonenzymatic cyanogen bromide cleavage as well as other proteases such as ArgC, AspN, GluC (bicarbonate), GluC (phosphate), and chymotrypsin are also suitable. Various peptide mass databases are designed to reflect each unique cleavage point. A gel plug no larger than the stained protein spot is excised either manually or robotically. The gel piece is then washed to remove detergents and other confounding materials followed by reduction and alkylation of cysteine residues. The gel is dried and rehydrated by the addition of buffered protease, the protein is digested (often overnight), and the peptides are extracted from the gel piece(s). After extraction, the peptides can be concentrated, desalted, and eluted using microcolumn chromatography.

MALDI-MS is the most commonly used technique to perform PMF [38,39]. MALDI-MS is a rapid, reasonably robust, easy to perform, sensitive (low femtomole range), and accurate (low ppm range) identification tool. It is reasonably tolerant to contaminants, can be automated, and detects singly charged (protonated) peptide

ions. Although PMF is a useful tool for identifying relatively pure proteins, it is less effective in analyzing protein mixtures. Separation of complex protein samples by high resolution 2DE is typically well suited for PMF. However, the presence of comigrating, and thus overlapping, proteins (those with similar pI and MW) resolved at similar coordinate positions presents problems for PMF, particularly in small format slab gels, and unequivocal identification is frequently difficult. This situation is exacerbated in 1D separations where single-stained bands may contain large numbers of different proteins with similar mass.

When protein identifications obtained by PMF are ambiguous, sequence-specific peptide fragmentation and sequence searching are necessary. Significant improvements in protein identification in gel plugs have occurred with the implementation of peptide fragmentation induced by collision-induced dissociation (CID)-MALDI-MS/MS. Instruments such as MALDI-ion traps, MALDI-Q-TOF (MALDI quadrupole time of flight), and MALDI-TOF/TOF are particularly suitable for this purpose. Alternatively and more frequently, electrospray ionization tandem mass spectrometry (ESI-MS/MS) and nanoelectrospray ionization tandem mass spectrometry (nanoESI-MS/MS) are being used to achieve sequence information and unambiguous identification of 2DE gel cutouts.

10.3.1.8.3 Electrospray ionization mass spectrometry (ESI-MS). The alternative to solid-phase peptide MALDI-MS is ESI-MS of liquid-phase analytes [40]. ESI separation is based on very low flow rates of peptide eluents from high performance liquid chromatography (HPLC) columns for LC/MS or capillary electrophoresis (CE) columns for CE/MS into a nanoelectrospray ion source that evaporates the solvent and creates multiply charged ions in a droplet cloud. Various voltages are applied to the quadrupole electrodes to direct the ions toward the mass analyzer and along the way, trap and eject them according to their mass-to-charge ratios. The linear quadrupole mass analyzer thus acts as a mass filter by varying potentials on the quadrupole rods to pass only a selected mass-to-charge ratio. Ions are ejected in order of increasing mass-to-charge (m/z) ratio and detected by the ion detector resulting in a precise m/z spectrum.

One of the advantages of ESI relates to the multiply charged species it generates. Because the average charge state increases in an approximately linear fashion with MW, the true molecular mass of an ion can be calculated since more than one charge state is observed. Furthermore, multiple quadrupoles can be added in tandem (MS/MS) to make multiple ion interpretation more robust and facilitate peptide sequence analysis. For example, in a triple-quadrupole instrument, peptide ion masses are measured by the first quadrupole, a peptide of interest is sent to the second quadrupole where it is fragmented by CID, and the fragment masses are measured at femtomole levels in the third quadrupole. For peptide mass mapping, the mass information from several peptides derived from the same protein is required for protein identification by database searching. In contrast, the CID spectrum of a single peptide can contain enough information for unambiguous identification of a protein. It is a direct result of this technical development that has now made it possible to identify the components of even relatively complex protein mixtures without prior purification of individual proteins by using two-dimensional chromatography methods coupled to ESI-MS/MS. The identification (and quantification) of proteins using this technology is discussed in Sections 10.4.1.2.3 and 10.4.1.2.4.

10.3.2 Contemporary Improvements in 2DE Applications

The combination of 2DE and MS constitutes a powerful platform for protein expression analysis. Unfortunately, first-generation 2DE has several shortcomings that have spawned a number of chromatographic and MS approaches designed to overcome these deficiencies and render protein expression analysis truly global. The major weaknesses of the 2DE approach include its inability to resolve very hydrophobic proteins and those with extremes of pI (particularly basic proteins). The hydrophobicity issue is difficult to overcome [41,42], as it is in all proteomic approaches [43] using aqueous analytical systems. Another major problem that has limited 2DE's applicability is its poor dynamic range, meaning that it cannot detect simultaneously all levels of protein expression and MW. Finally, 2DE has failed to gain a broad-based, solid foothold in the pharmaceutical industry because it is so difficult to automate and generate reproducible results. Despite technical developments and attempted innovations, 2DE remains laborious, technically demanding, and low throughput. Virtually all successful developments in differential protein expression analysis, which include automation and consequent increments in throughput, have taken place through emerging gel-free, LC and MS technologies, and 2DE has been all but eliminated from the proteomic approach in large-scale, pharmaceutical applications.

10.3.2.1 Two-Dimensional Difference Gel Electrophoresis (2D-DIGE). One technical development that has successfully addressed both the sensitivity and reproducibility issues facing 2DE is a technique called *fluorescent two-dimensional difference gel electrophoresis* (2D-DIGE) [44]. This approach was developed to enable the separation and differential expression analysis of two or more samples on a single gel. This technique has been reviewed thoroughly [45–47], so a detailed description is not given here. Despite its own limitations [48], 2D-DIGE approach overcomes most gel variability issues and can be quite useful in experiments with limited numbers of samples.

In DIGE (Fig. 10.3), complex protein samples are labeled with spectrally distinct fluorescent cyanine dyes Cy2, Cy3, and Cy5 and the samples mixed, so that they can be examined in a single 2D gel with each dye giving an independent channel of measurement of the co-resolved spots. Protein samples can be labeled in two ways: “minimal” labeling of the ϵ -amino group of the lysine residues, a roughly 5% labeling efficiency, and “saturation” labeling of all available cysteines in the protein mixture. For each spot detected in the gel pattern, the intensities in the respective dye channels are compared and ratios are calculated from these intensities to indicate the extent of differential protein expression. With DIGE, the uncertainty of coordinate gel matching across two or more gels (e.g., are you correctly matching the same spot in different gels?) is overcome, for the most part. For instance, this approach enables labeling of two experimental groups with either Cy3 or Cy5 dyes with the inclusion of a Cy2-labeled internal standard composed of an equal mixture of the two experimental samples, and all three are thus present on each gel of a multigel experiment. Because the individual samples (labeled with Cy3 or Cy5) are multiplexed with an equal amount of the same Cy2 internal standard, proteins missing from one or the other sample are present and detectable in each analytical gel. Consequently, Cy3: Cy2 and Cy5: Cy2 ratios can then be calculated in each individual gel pattern, obviating the gel to gel variability inherent in one-sample-per-gel, first-generation 2DE systems. This affords the DIGE approach very low technical (analytical) noise and high statistical power [49].

Figure 10.3 2-D DIGE experiment with three fluorescent dyes. Samples A and B are labeled with either Cy3 or Cy5, but a pooled internal standard is also constructed from equal amounts of all the samples in the experiment and labeled with Cy2. After mixing these protein samples and performing 2DE, the respective protein spot patterns can again be visualized by illuminating the gel with the specific excitation wavelengths. The protein spot intensities of samples A and B can now be normalized by dividing each spot intensity by the corresponding spot intensity of the pooled internal standard. Analyzing these normalized spot intensities enables the detection of more subtle differences in protein expression levels with a higher statistical confidence. *Source:* With permission from the Thomson Reuters publication: Witzmann FA, Bai F, Hong D. *et al.* Gels and more gels: probing toxicity. *Curr Opin Mol Therapeut* 2004;6:608–615. (See color insert.)

10.3.3 2DE Applications in Drug Discovery, Development, and Toxicity

Given 2DE's fundamental limitations and its relative ineffectiveness as a high throughput application, its once widespread use in drug discovery and pharmacoproteomics has been augmented and in many cases supplanted by LC-MS-based technologies. For the most part, 2DE remains a useful tool, albeit in more focused applications. Nonetheless, gel-based proteome profiling has been applied to the analysis of preclinical drug effects on gene expression as well as the discovery of potential protein targets, thus making significant contributions to drug discovery. The approach involves proteome profiling to identify and validate disease-specific proteins, identification and candidate target assignment, lead-compound identification and evaluation, mode of action assessment, and formal drug toxicology studies [50,51].

For instance, 2DE has been instrumental in the discovery of early markers of drug toxicity [50], including the development of a chimeric mouse model for prediction of idiosyncratic drug toxicity *in vivo* in preclinical studies [52]. This approach has facilitated the development of surrogate markers to determine the activity of SMTKIs (small-molecule tyrosine kinase inhibitors) designed to produce an antitumor effect [53]. Owing to its ability to resolve charge-modified proteins, 2DE has been integral in the development of efficient and sensitive analytical methods for the separation, identification, and quantification of drug–protein adducts that have important clinical and toxicological implications [54].

2D-DIGE has been used in a variety of ways, including the characterization of antifungal drug resistance [55]; assessment of antineovascular therapy with liposome drug delivery systems targeted to specific vascular proteins [56]; discovery of potential biomarkers and drug targets for sepsis-induced acute renal failure [57]; characterization of the antineoplastic activity, drug resistance, and unexpected toxicity in nonHodgkin lymphoma (NHL) Raji cells of the antitumor drug adriamycin at the mitochondrial proteomic level [58]; and the identification of early changes in protein expression associated with cisplatin ototoxicity [59]. This approach has also led to the identification of various potential cancer biomarkers for the development of diagnostic tests and therapeutic targets [60]. In addition, proteome profiling including gel-based approaches has been used to determine protein markers indicative of therapeutic efficacy or toxicity for lead-compound prioritization in the development of effect antibacterial agents [61]. Such studies specifically investigated adaptation networks that are crucial for bacterial survival and emphasized the characterization of the stress response to antibiotic treatment.

10.4 LIQUID CHROMATOGRAPHY MASS SPECTROMETRY (MS)-BASED PROTEOMIC ANALYSIS

MS-based proteomic technologies have become widely applied analytical tools for protein identification and quantification in complex biological samples. Although some successes using this approach for protein quantification have been reported, it remains technically difficult to comprehensively characterize the global proteome. The main stream of this approach is to use stable-isotope-labeled tags to derivatize proteins and then analyze tryptic digests by MS/MS. However, owing to the high costs of the labeling reagents and the nature of the methodology [e.g., in isotope-code affinity tag (ICAT)

approach, proteins without cysteine residues cannot be labeled and thus cannot be measured], this platform has gradually lost its popularity in recent years. Furthermore, chromatographic shifts can make quantitative analysis of differentially labeled peptides computationally difficult and error prone, and simultaneous quantification of proteins from multiple sample sets is problematic due to the limitation of available labeling reagents. In recent years, the ion-intensity-based label-free quantitative approach has gained more attention as mass spectrometer performance has improved significantly. It provides a powerful tool to identify and quantify thousands of proteins from a complex biological sample in a single assay.

10.4.1 LC/MS-Based Quantitative Proteomics Platforms

10.4.1.1 Stable-Isotope-Labeled Protein Quantification Approaches. Quantification of protein expression and determination of differences between two or more physiological conditions, such as diseased or healthy, are challenging tasks in proteomics. Several MS-based techniques for quantitative protein expression analysis have been developed and applied successfully in recent years [62–69]. Since MS is not intrinsically quantitative, strategies have been developed that enable detection of protein abundance changes using mass tags. ICAT (for relative quantification) [70] and AQUA (for Absolute QUAntification) are two good examples of these methods [71].

ICAT is a widely used quantitative method for large-scale protein quantification. In this method, sulfhydryl groups of cysteine residues are derivatized by either “light” or “heavy” isotope tags (Fig. 10.4) after protein extraction, with control and experimental samples being derivatized separately (Fig. 10.5). Chemical incorporation of isotope tags allows for both identification and quantification of ICAT peptide pairs [70]. While there are many advantages of using ICAT for global quantitative protein analysis, including enrichment of cysteine-containing peptides through biotin–avidin affinity selection that reduces sample complexity for MS analysis, it is important to realize that this technology is dependent on the presence of cysteine residues, as their sulfhydryl groups are chemically modified in proteins. Proteins that lack cysteines will not be

Figure 10.4 Chemical structure of ICAT reagents.

Figure 10.5 Schematic illustration of ICAT method. Proteins in both control and experimental samples are first separately labeled by “light” and “heavy” ICAT reagents. The labeled samples are then mixed and digested by trypsin. Tryptic peptides are affinity-selected using an avidin column followed by mass spectrometric analysis to determine the protein identity and relative quantity.

derivatized by ICAT reagents, thus this technology is not suitable for proteins lacking Cys residues (~10% of a proteome). Other stable isotope labeling technologies include SILAC (labels amino acids in cell culture) [72], iTRAQ (uses isobaric tags), and ^{18}O labeling [73].

AQUA, also known as *Absolute QUAntification of proteins*, is achieved by spiking internal standards (e.g., a peptide of interest) of known quantity to a protein digest to be analyzed, where stable-isotope-labeled “heavy” synthetic peptide(s) serves as internal standard(s) for peptide quantitation (Fig. 10.6). Quantification is carried out by calculating the intensity ratio between the endogenous peptide and the reference “heavy” peptide, which share the same chemical and physical properties including chromatographic retention time, ionization efficiency, and fragmentation pattern, but differ in mass (depending on the design of the quantification standards) [74]. While this approach is attractive for absolute quantification of proteins, a number of limitations still exist, such as (i) a very limited number of proteins can be quantified in a single experiment; (ii) amount of labeled standard needs to be accurately measured before spiking; (iii) tryptic digestion efficiency is not taken into account, leading to inaccurate quantitative measurement; and (iv) ambiguity in peptide identification and quantification because of the presence of multiple isobaric peptides in a tryptic digest. Some of these issues can be resolved by selected reaction monitoring (SRM) or multiple reaction monitoring (MRM) (Section 10.4.3) in combination with a stable-isotope-labeled intact

Figure 10.6 AQUA strategy for absolute protein quantification. After initial MS/MS run to determine the peptide of interest, an isotope-labeled analogous peptide is synthesized and a known quantity of this peptide is spiked into the protein mixture followed by tryptic digestion. Absolute quantity of the endogenous peptide is determined by comparing native peptide MS signal to "heavy" AQUA peptide signal.

protein [75–78]. QCAT [79] and PSAQ [77] are other two commonly used methods for absolute quantification.

10.4.1.2 Label-Free Protein Quantification Approaches. Label-free and signal-intensity-based relative protein quantification shotgun proteomics approaches are promising alternatives to stable isotope labeling approaches and have been applied to quantify differentially expressed proteins from complex biological samples [63,80–82]. One approach is to directly compare peptide peak areas between LC/MS runs. This approach is simple and cost-effective and has demonstrated high reproducibility and linearity comparing peptide level or protein abundance. Inclusion of statistical analysis with this method allows detection of small but statistically

significant changes that are biologically important. Several studies have demonstrated that extracted ion chromatograms (XICs) of selected peptide ions correlate well with protein abundances in complex biological samples [63,80–82]. Another label-free method, referred to as *spectral counting*, compares the number of MS/MS spectra assigned to each protein [83]. One advantage of the spectral counting method lies in its ability to measure relative abundances of different proteins in the same biological system as shown by significant correlations between spectral counts and independent estimates of protein copy number in yeast [84]. However, the application of these methods, especially to mammalian systems, requires more robust computing power and algorithms capable of handling chromatographic peak alignment and peptide ion intensity measurements for analyzing changes in protein abundances in complex biological samples.

All label-free LC/MS-based protein quantification methods include four fundamental steps as depicted in Fig. 10.7: (i) sample preparation—protein extraction, reduction, alkylation, and digestion; (ii) sample separation and analysis—(LC and MS/MS); (iii) data analysis—identification, quantification, and statistical analysis; and (iv) data interpretation—protein–protein interaction network and pathway analysis.

10.4.1.2.1 Sample Preparation. For MS analysis, in general, proteins are extracted from tissues, cultured cells, or biofluids in freshly made lysis buffer containing 8 *M* urea and a reducing agent (e.g., 10 mM DTT). For tissue culture cells grown in six-well plates, culture media are first removed by aspiration. Then 100 μ L of lysis buffer is added to each well and cells are lysed by pipetting. Lysed cells are transferred to microcentrifuge tubes and incubated at room temperature with gentle agitation. Unlysed cells and insoluble particles are removed by centrifugation (12,000 *g* for 5 min) before protein assay. To analyze the same amount of proteins from each sample, protein concentrations from all samples must be measured by Bradford assay [85]. The same lysis buffer should be used as the background reference for the protein assay to obtain a relatively accurate measurement among all samples (because of the presence of urea in lysis buffer).

Resulting protein extracts are subsequently reduced and alkylated with DTT and iodoacetamide to block protein sulfhydryl groups. However, in certain instances, volatile reagents such as triethylphosphine and iodoethanol are used [86]. This volatile reduction and alkylation protocol enable all sample preparation steps to be carried out in one tube without washing, filtering, or sample transfer, which minimizes sample preparation variations. Protein mixtures are then digested by trypsin. Dried pellets

Figure 10.7 Label-free protein quantification technology workflow.

are resuspended in 500 μL of 100 mM ammonium bicarbonate buffer containing 2 μg of trypsin and incubated at 37°C overnight. Protein to trypsin ratio is 50:1, and urea concentration should be below 1.6 M (higher urea concentration inhibits trypsin activity). Tryptic digests are filtered with 0.45 μm spin filters to avoid micro- or nanocolumn clogging.

10.4.1.2.2 Mass Spectrometric Analysis. All digested samples should be randomized for injection in order to remove systematic bias from data acquisition. Typically, up to 20 μg of the tryptic peptides is required for injection onto a C18 microbore column (i.d. = 1 mm, length = 5 cm) and $\sim 2 \mu\text{g}$ for a nanoflow column (i.d. = 75 μm , length = 5 cm). Peptides are eluted with a linear gradient from 5% to 45% acetonitrile developed over 120 min at a flow rate of 50–200 $\mu\text{L}/\text{min}$ (microflow) or $\sim 300 \text{ nL}/\text{min}$ (nanoflow), and effluent is electrosprayed into an LTQ linear ion-trap mass spectrometer (Thermo-Fisher Scientific). The ESI source is operated with 4.8 kV potential, a sheath gas flow of 20 arbitrary units, and a capillary temperature of 225°C. Maximum ion time is set to 50 ms for parent ion scan and 500 ms for zoom scan and MS/MS scan. This method requires that all the MS data is collected in the data-dependent mode (e.g., triple-play mode) as shown in Fig. 10.8 (MS scan, zoom scan, and MS/MS scan). Parent ion scans and MS/MS scans are collected in centroid mode and zoom scans in profile mode. Dynamic exclusion is set to a repeat count one, exclusion duration of 120 s, and rejection widths of $-0.75m/z$ and $+2.0m/z$. The acquired data are filtered and analyzed by special algorithms such as the one developed by Higgs *et al.* [87]. Database searches against protein databases (e.g., the International Protein Index and/or the NCBI nonredundant databases) are carried out using database search engines such as SEQUEST™ and X!Tandem algorithms. Protein quantification is also often carried out using special algorithms [87]. Briefly, once the raw files are acquired from the LTQ, all XICs are aligned by retention time (Fig. 10.9). To be used in the protein quantification procedure, each aligned peak must match parent ion, charge state, daughter ions (MS/MS data), and retention time. After alignment, the area under the curves (AUCs) for individually aligned peaks from identified peptides from each sample are computed; the AUCs are then compared for relative protein abundance (Fig. 10.10).

10.4.1.2.3 Protein Identification. Proteins identified by SEQUEST and X!Tandem are generally categorized into priority groups on the basis of the quality of the protein identification. The Peptide ID Confidence classifies a protein as “HIGH” or “MODERATE” based on the peptide identification confidence. Proteins with at least one peptide having a confidence between 90% and 100% are assigned to the HIGH category regardless of whether there are other peptides having low confidence. Proteins with at least one peptide having a confidence between 75% and 89% are assigned to the MODERATE category. All peptides with confidence less than 75% are filtered out by the software before further analysis. SEQUEST and X!Tandem database search algorithms are used for peptide sequence identification. Each algorithm compares the observed peptide MS/MS spectrum and a theoretically derived spectra from the database to assign quality scores (*XCorr* in SEQUEST and *E-Score* in X!Tandem). These quality scores and other important predictors are combined in the algorithm that assigns an overall score, %ID Confidence, to each peptide. The assignment is based on a random forest recursive partition supervised learning algorithm [88]. The %ID

Figure 10.8 “Triple-play” MS method. After the effluent is electro-sprayed into a mass spectrometer, primary MS scans are acquired for peptide mass determination, followed by zoom scans for charge state determination, MS/MS scans for peptide sequence determination, and database searching for protein identification. Every peak above the ion intensity threshold will be selected for “triple-play.” *Source:* Adapted with permission from Wang M, You J, Bemis KG, *et al.* Label-free mass spectrometry-based protein quantification technologies in proteomic analysis. *Brief Funct Genomic Proteomic* 2008;7:329–339.

Figure 10.9 Chromatographic peak alignment. This process requires all landmark peaks matching peptide mass, charge state, MS/MS spectra, and retention time within a pre-determined window (1-min in most cases) crossing all analyzed samples. The bottom figure shows how well all the peaks are aligned after this process.

Confidence score is calibrated so that approximately $X\%$ of the peptides with %ID Confidence greater than $X\%$ are correctly identified.

The confidence in protein identification is increased with the number of distinct amino acid sequences identified. Therefore, proteins are also categorized depending on whether they have only one or multiple unique sequences of the required confidence. In general, priority assignments reflect the level of confidence in the protein identification. Priority 1 proteins would have the highest likelihood of correct identification and priority 4 proteins the lowest. This priority system is based on the quality of the amino acid sequence identification (Peptide ID Confidence) and whether one or more sequences are identified (Multiple Sequences). Many would view any protein identification outside priority 1 as questionable [89]. A highly parallel processing computing cluster and data qualification and filtering software are required for data processing and analysis.

10.4.1.2.4 Protein Quantification. One of the keys for protein quantification in label-free methods is chromatographic peak alignment because multiple injections of the samples onto the same HPLC column in large biomarker studies can produce chromatographic shifts. Unaligned peak comparison will result in larger variability and inaccuracy in peptide quantification [87]. A graphical example of a comparison of peptide quantities across a complex biological sample is shown in Fig. 10.10. All peak intensities are transformed to a $\log_2$ scale before quantile normalization [90]. Quantile normalization is a method of normalization that essentially ensures that every sample has a peptide intensity histogram of the same scale, location, and shape. This normalization procedure removes trends introduced by sample handling, sample preparation, total protein differences, and changes in instrument sensitivity while running multiple samples. If multiple peptides have the same protein identification, then their quantile

Figure 10.10 Peptide quantification by extracted ion chromatograms (XIC). XIC from (a) control and (b) treated samples: black lines are the raw XICs, from the experiment, whereas light and dark gray lines are smoothed XICs, with dark gray lines being the 2-min window of chromatographic alignment. (c) The relative quantity of the peptide of interest (as indicated by arrows in (a) and (b)) can be calculated and compared by integrating the area-under-the-curve (AUC). *Source:* Adapted with permission from Wang M, You J, Bemis K, *et al.* Label-free mass spectrometry-based protein quantification technologies in proteomic analysis. *Brief Funct Genomic Proteomic* 2008;7:329–339. (See color insert.)

normalized $\log_2$ intensities are averaged to obtain $\log_2$ protein intensities. The average of the normalized log peptide intensities is a weighted average. A peptide is weighted proportionally to the Peptide ID Confidence for its protein category and receives a weight of zero if it is outside that category. For example, peptides with less than 90% confidence contribute zero quantitative weight to a HIGH category protein. The log

transformation serves two purposes. First, relative changes in protein expression are best described by ratios. However, ratios are difficult to statistically model and the log transformation converts a ratio to a difference, which is easier to model. Second, as is frequently the case in biology, the data better approximate the normal distribution on a log scale [91]. This is important because normality is an assumption of the ANOVA (Analysis of Variance) statistical model used to analyze the data. The base of the log transform is arbitrary, with base 2 being the most common with genomic data. Base 2 is popular because a twofold change (or doubling, or 100% increase) yielding an expression ratio of 2 is transformed to 1 on a log base 2 scale (i.e., a twofold change is a unit change on the log base 2 scale). The $\log_2$ protein intensity is the final quantity that is fit by a separate ANOVA model for each protein shown below:

$$\log_2(\text{intensity}) = \text{overall mean} + \text{group effect (fixed)} + \text{sample effect (random)} \\ + \text{replicate effect (random)}$$

In this model, group effect refers to the effect caused by the experimental conditions or treatments being evaluated. Sample effect represents the random effects from individual biological samples. It also includes random effects from sample preparation. The replicate effect refers to the random effects from replicate injections of the same sample. Therefore, all the injections should be randomized and the instrument operated by the same operator for a particular study. The inverse $\log_2$ of each sample mean is calculated to determine the fold change (FC) between samples.

10.4.1.2.5 Statistical Analysis. The number of significant changes between groups, the FCs, and the variability (coefficient of variation) for each protein can be determined from ANOVA. The threshold for significance is set to control the false discovery rate (FDR) for each comparison at an investigator-desired percentile, normally 5% [92]. The FDR is estimated by the q -value, which is an adjusted p -value. The FDR is the proportion of significant changes that are false positives. If proteins with a q -value ≤ 0.05 are declared significant, it is expected that 5% of the declared changes will be false positives. In this method, the p -value to q -value adjustment is done separately for priority 1, priority 2, and the LOW confidence categories.

FC is computed from the means on the AUC scale (antilog) as follows:

$$\text{FC} = \frac{\text{Mean treated group}}{\text{Mean control group}} \\ \text{When mean treated group} \geq \text{mean control group (upregulation)} \\ \text{FC} = \frac{\text{Mean control group}}{\text{Mean treated group}} \\ \text{When mean control group} > \text{mean treated group (downregulation)}$$

Absolute FC = $|\text{FC}|$ = absolute or positive value of the FC

An FC of 1 means there is no change. Also, the median % coefficient of variation (%CV) for each priority level is determined. The %CV is the standard deviation divided by mean on a percentage scale. The %CV is given for both the replicate variation and the combined replicate plus sample variation.

10.4.1.2.6 Quality Assurance and Quality Control. To assess the stability of the HPLC system and MS instrument, a known purified standard protein or stable-isotope-labeled synthetic peptide is commonly spiked into every sample at a constant amount as an internal reference for assessment of technical variations before tryptic digestion. Several considerations should be given for the selection of the standard: (i) the protein/peptide must not come from the same species as the sample of interest, (ii) a series of signature peptides should be easily detected and identified by the instrument, and (iii) the amount of the standard spiked into each sample should be comparable to the amount of median abundant proteins in the sample. After global protein identification and quantification, these peptides and their relative quantities should be inspected for QA/QC purposes.

10.4.1.3 LC/MS-Based Targeted Proteomic Analysis. Although the global quantitative expression proteomics is used extensively as the principal platform for biomarker discovery, it is costly in terms of lengthy MS data acquisition and analysis time. To facilitate more rapid quantitative analysis of larger, clinically relevant sample sets ($n > 100$), the MS-based targeted proteomics technologies such as multiple-reaction-monitoring (MRM) are becoming the more popular platforms for verification and validation of potential biomarkers [93]. MRM is not a new technology; it has been used widely for over 30 years in small-molecule drug metabolism studies [94–98]. Only recently, the MRM assay approach with new-generation linear ion-trap mass spectrometers has been developed to measure specific peptides in complex biological mixtures such as human plasma or serum for targeted proteomic analysis (Fig. 10.11) [93,99–104]. This approach is based on the selection of specific peptide(s) to be used as stoichiometric representatives of a protein [93]. Protein content can be quantified by comparing the peptide peak area with a stable-isotope-labeled internal standard [101]. MRM is an MS/MS scan mode unique to triple-quadrupole mass spectrometers that are capable of rapid, sensitive, and specific quantification of a set of targeted molecules in highly complex samples [93]. When combined with the use of stable-isotope-labeled synthetic peptide standards, MRM analysis is capable of sensitive and absolute quantification of peptides of interest across a wide concentration range (10^3 – 10^4).

10.4.1.3.1 Selection of Peptide of Interest. Protein quantitative assay development based on proteolytic peptide surrogates requires that the peptides of interest selected are both easily detectable in every sample and are reproducible in MS measurements. Selection of a peptide to represent a protein in an MRM assay is a crucial step that can dramatically affect the ultimate sensitivity and specificity of an assay. When selecting a target peptide, the following factors must be considered: (i) the peptide amino acid sequence must be unique to the target protein and should not contain missed cleavage sites, (ii) the peptide should be reproducibly observed in proteolytic digests of every sample, (iii) the peptide should not contain amino acids that are susceptible to PTMs (e.g., Cys, Met) unless the purpose of the assay is to analyze PTMs, and (iv) the peptide length should be in the range of 7–30 amino acids to accommodate the m/z range of the triple-quadrupole instrument.

10.4.1.3.2 MRM Transition Determination. Design and validation of hundreds of MRM transitions for the quantitative analysis of the target peptides in complex biological samples are two major determining factors for the fate of the assay. When working

Figure 10.11 Schematic of the MRM scanning on a triple quadrupole mass spectrometer. The targeted precursor ion is selected in the first quadrupole (Q1) and enters the second quadrupole (Q2) where it undergoes collision-induced dissociation (CID) (fragmentation). One or more diagnostic fragment ions (product ion) are then selected in the third quadrupole (Q3) according to the predefined MRM transitions (TS) (e.g., m/z 534 precursor ion $\rightarrow$ m/z 375 product ion). Quantification is achieved by integrating area-under-the-curve (AUC) from extracted ion chromatogram (XIC) of the MRM ion-pair. For absolute quantification, a synthetic isotopically labeled peptide standard is required to optimize MS parameters and to generate a standard curve.

with a species where the genome has been completely sequenced (e.g., *Homo sapiens*), publicly available MS/MS spectra databases (e.g., Global Proteome Machine & Peptide Atlas) are very useful for determining which tryptic peptides and their fragment ions should be selected and are experimentally frequently observed with relatively high ionization efficiency [105]. However, when such databases are not available, *in silico* methods such as MRMAid and Skyline can be used to assist the determination of the MRM transitions [106,107]. Commercially available software packages capable of creating the most appropriate MRM transitions include MRMPilot (Applied Biosystems), QuanOptimise (Waters), SRM Workflow (Thermo-Fisher), and MassHunter Optimizer (Agilent). These methods generally employ fairly complicated algorithms based on a combination of theoretical rules and empirical observation for optimal peptide MS/MS. However, to date there is no computer algorithm-based method that can accurately and reliably generate MRM transitions. All MRM transitions generated by *in silico* methods still need to be experimentally validated. Optimization often is required to facilitate the development of sensitive and accurate MRM assays that are capable of detecting endogenous levels of proteins in “real” biological samples, essentially eliminating false positives. This optimization stage involves the use of standard protein(s) or peptide(s) for the establishment of the peptide eluting time window and the standard curve for quantification.

10.4.1.3.3 MS Analysis. For MRM assays, an autosampler (e.g., Agilent 1100 autosampler), an HPLC system (e.g., Agilent 1100 LC system), and a triple-quadrupole mass spectrometer (e.g., AB/MDS SCIEX 4000 QTrap) are required. If possible, three unique peptide analytes per protein and three MRM transitions per peptide should be monitored in order to obtain confirmatory and/or qualitative information in addition to the quantitative data. A triple-quadrupole instrument can monitor a large number of transitions simultaneously (~ 80 different MRM transitions) and still achieve the reasonable number of points per chromatographic peak for accurate quantitation. Typically, 10 points per LC peak are required to achieve reasonable %CV's ($< 10\%$). When an instrument is operated in MRM mode, predetermined MRM transitions (~ 20 ms dwell time per transition) trigger data-dependent scans. MS/MS spectra are first acquired and used to confirm all the specific MRM ion pairs (to minimize false positives). For QA/QC purpose, a constant known amount of standard (e.g., chicken lysozyme digest) should be spiked into each sample before the digestion step.

10.4.1.3.4 Quantification and Data Analysis. MRM-based analysis provides significant improvement in sensitivity and specificity compared to the IDA (information-dependent acquisition) method for analyzing a specific set of target proteins. However, designing and running MRM assays for relative or absolute protein quantitation require considerable instrument time and sample replicates for improved reproducibility, especially for low abundance proteins. Specific software such as MultiQuant 1.0 (Applied Biosystems) with the MQL algorithm is required to determine AUC for MRM ion pairs for peptide quantitation. A standard curve is needed to assess LOD (limit of detection) and LOQ (limit of quantification) [108,109]. Stable-isotope-labeled (^{15}N and/or ^{13}C) internal standard peptides (iSTDs) and standard calibration curves are normally used for absolute quantification of selected peptides in a complex mixture (Fig. 10.12). A three-day spike-recovery experiment to estimate the working range of the assay is often performed. Serial dilutions of synthetic standard peptides are made in a matrix

Figure 10.12 An Example of a statistically validated standard curve. Serial dilutions of the SIL (stable isotope labeled) peptide is monitored by MRM; Concentration points (black circles and dark gray diamonds) represent two calibration series (with known peptide concentrations). When Cal A is used to establish the calibration curve, Cal B can be used for validation, and *vice versa*.

(e.g., horse plasma), which lacks the target peptide(s). The purpose of using a matrix is to mimic the complex biological environment that can lead to a chromatographic shift (in comparison with purified standard peptide mixture). Overall working range (e.g., lowest concentration to highest concentration with %CV < 10%), assay accuracy (absolute value of % relative error < 10% for lowest limit), and the overall assay performance (overall %CV) can be determined from this curve. Once the standard calibration curves are established, stable-isotope-labeled iSTDs are synthesized and used for normalization of sample-to-sample variations within an assay during the course of sample preparation and handling and are used for statistical validation of the standard curves. All the standard peptides (labeled or unlabeled) are designed, so they will have at least five additional amino acids flanking each N- and C-terminal (the so-called extended standard peptides). This is to minimize the effects of trypsin digestion efficiency, which can lead to inaccurate quantitation of the peptides [75]. A different matrix (e.g., *E. coli* extracts) can be used to test the matrix effect if necessary.

As mentioned earlier, because the data has multiple sources of random variation, a Linear Mixed Model (a generalization of ANOVA) is used for biostatistics analysis in MRM studies. This model, especially when applied to complex experimental designs, cannot be handled by introductory methods such as *t*-tests. Also, the exact scale of protein expression used in the model can affect the sensitivity. In general, there is usually a large technical variation introduced by the act of “measurement” in many “omics” studies. Randomization of measurement order and normalization of the data eliminate these technical biases.

10.4.2 Data Interpretation

To understand the biological significance of the protein expression or modification changes, the results including protein IDs and FCs from the LC/MS analysis can be analyzed using protein classification, protein–protein interaction, and/or biological pathway analysis software. These software packages enable the creation of protein–protein interaction networks, biological pathways, and gene regulation networks from a data set, which in turn enable one to understand specific biological processes that are involved in a particular study and identify biomarker candidates. Correlation analyses of genomic, proteomic, metabolomic, and phenotypic data are also often conducted to elucidate specific molecular signatures for certain biological conditions.

10.4.3 MS-Based Quantitative Proteomics Applications in Drug Discovery and Development

In recent years, the MS-based proteomics technologies have become major focuses in drug target identification and quantitative proteomics [110–112]. The ability to accurately identify, quantify, and characterize protein expression levels and modifications under different biological conditions in order to diagnose a disease has enabled the identification of new pharmacological targets for therapeutic intervention. For example, Herceptin is used to treat patients with metastatic breast cancer. This monoclonal antibody binds HER2. Patients with over expressed HER2 in their tumors can be effectively treated by Herceptin, while breast cancer patients with normal HER2 expression will not benefit from this treatment [113,114]. Another example is gefitinib (IRESSA) treatment of nonsmall-cell lung cancer (NSCLC). Even though a large phase III ISEL

(IRESSA Survival Evaluation in Lung Cancer) trial demonstrated some improvement in survival with gefitinib, it failed to reach statistical significance compared with placebo in the overall population and in patients with adenocarcinoma. Interestingly, in subgroup analyses, a significant increase in survival was observed with gefitinib treatment in patients of Asian origin and in nonsmokers [115]. Biomarker data analysis from a subset of patients in this trial suggested that patients with epidermal growth factor receptor (EGFR) mutations have a higher chance of survival when treated with gefitinib. Thus, it is important to classify patients with NSCLC based on EGFR mutation status in order to benefit those who will be more responsive to the treatment with gefitinib.

MRM-based applications in diagnostics and drug development include the measurement of C-reactive protein in serum [101], prostate-specific antigen (PSA) in serum [104], fibulin-2 for breast cancer in a mouse model [116], and carcinoembryonic antigen in lung cancer [117]. One early example of the use of MRM for absolute quantification of protein expression is a study carried out on cytochrome P450 (CYPs) enzymes in human liver [118]. CYPs are responsible for the metabolism of most therapeutic drugs, and while they are not classified as biomarkers of diseases, their expression levels can be highly induced by a wide range of drugs [119]. Thus, they are routinely monitored during preclinical safety assessment within the pharmaceutical industry due to the risk of initiating adverse drug reactions (ADRs) [120]. MRM assays have also been used as tools for protein modification profiling [121–123].

The key point in the development of protein biomarkers is to ensure accurate and reproducible data collection and analysis processes with the use of techniques such as peak alignment and subsequent statistical modeling. The most important aspect is the integration of clinical and proteomic data to facilitate the search for protein biomarkers that allow for the prediction of treatment outcomes in clinical applications and drug discovery. Hopefully, this will bring us a step closer to practical medicine.

10.5 PROTEIN MICROARRAY

Protein microarray is a new platform that has become more accessible to researchers for quantitative identification of protein signatures to discriminate between normal and disease samples. The value of this platform in drug discovery is highlighted through the identification of ligands that offer not only excellent potency but also good selectivity. It can also be used in high throughput fashion for drug screening [124]. Protein microarrays offer the potential for more sensitive, specific, and high throughput analyses of the proteome [125,126]. Using specific antibodies, targeted antigens can be quantitatively mapped simultaneously in small, clinically relevant tissue or body fluid samples [126]. For example, tissue microarrays (TMAs) can be used to analyze hundreds of tissue samples simultaneously, thus represent attractive methods for high throughput detection of antigens of interest, especially in high throughput immunohistochemical studies [127–130]. Their applications include identification and validation of novel biomarkers for diagnostic and prognostic profiles [127,128,131,132]. Other array-based platforms are forward-phase protein microarrays (FPAs) and reverse-phase protein microarrays (RPAs) [133–137]. In FPAs, specific antibodies or bait molecules are fixed on a surface, which can then bind specific antigens from a complex protein mixture such as serum or tissue lysates [134]. In RPAs, analytes (e.g., cellular lysates) are immobilized

and probed with specific antibodies [135,136]. Since many analytes are present in low abundance, RPAs are particularly useful for the amplification of signals for detection by fluorescent-labeled secondary antibodies [136,137]. Both these arrays have been used widely in biomedical research, particularly for the identification of protein biomarkers [138–141]. However, the specificity of antibodies and quantification accuracy remain as two major obstacles in array-based proteomics [126].

10.6 BIOINFORMATICS

The development of powerful computational tools and bioinformatics resources has grown exponentially over the last decade, driven primarily by the need to convert information from biological discoveries into clinical applications and to identify significant correlations between a clinical phenotype and potential protein biomarker(s). With advances in bioinformatics, it is now possible to establish predictive models based on genomic, proteomic, and metabolomic data obtained from a defined set of clinical samples, allowing for the identification of drug target and/or protein biomarkers for diagnostics and prognostics. However, significant scientific and technical bottlenecks remain in data integration and in the analysis of complex biological systems. The lack of an intellectual framework that enables a better linkage of biological and clinical data to experimental outcomes has slowed our efforts on building predictive models that can diagnose and prognose disease and disease progression, and thus the ability to provide more precise biomarker(s) or drug target for biomedical research.

10.7 CONCLUSION

The goal of genomic and proteomic profiling is to obtain differential expression knowledge related to the patient samples being analyzed. The results from such an analysis uncover information about protein expression changes in the diseased state, providing the basis for biomarker discovery. Many believe that differentially expressed proteins can be used as molecular signatures for accurate predictive modeling. However, recent studies suggest that other factors such as environment and lifestyles can also play important roles in an individual's health [142]. Thus, integration of a great diversity of data sources from clinical, genomic, and proteomic to environmental and lifestyle must be established before accurate predictive modeling can be successful. Today, a comprehensive scientific method to interpret and understand clinical information and sophisticated molecular measurement data from a set of testing samples has not yet been fully developed. Our hope is that the integration of clinical data, biological data including pathways, cellular locations, and interacting partners, and better informatics tools will eventually make biomarker discovery more useful in building predictive models and supporting better health care.

11.1 SUMMARY

Many drugs used in clinical practice today are administered as a racemic mixture. As a consequence, these drugs can often be associated with complex pharmacokinetics and observed toxicities compared to drugs that are administered as a single enantiomer. It is well established that two enantiomers of a chiral drug commonly possess different pharmacological properties. In addition to variable pharmacodynamic properties, numerous studies have shown that the individual enantiomers of a chiral drug often display stereoselectivity in pharmacokinetics, toxicity, and drug disposition, particularly in the area of drug metabolism. This chapter attempts to provide a representative appraisal of the various stereochemical aspects associated with the metabolism and toxicity of chiral drugs.

11.2 INTRODUCTION

The study of the stereochemical aspects of chemicals began over 150 years ago when Louis Pasteur (1822–1895) discovered the optical isomerism of tartaric acid. In these

experiments, Pasteur observed that a sodium ammonium salt preparation of tartaric acid resulted in two distinguishable types of crystals [1]. When Pasteur separated the two types of crystals, dissolved each in water, and focused a beam of polarized light through the solution, the rotation of the polarized light was different for the two crystal specimens, where one solution rotated the light clockwise and the other counterclockwise. On the basis of these observations, Pasteur concluded that the two separated crystal forms of tartaric acid were either spinning to the right or to the left and neither could be superimposed on the other.

In chemistry, isomers (Greek *isos* = “equal”, *méros* = “part”) are defined as compounds with the same molecular formula but different structural formula. There are two types of isomers, constitutional isomers and stereoisomers. Constitutional isomers are molecules that differ from one another due to unique molecular connectivity and as a consequence, oftentimes do not share similar physical–chemical properties (Table 11.1). In contrast to constitutional isomers, stereoisomers are molecules that share the same molecular connectivity but differ in their spatial orientation. The principal structural basis of stereochemistry for organic molecules is associated with a tetrahedral atom, most commonly carbon. In this instance, a carbon atom with four different groups bonded to it is described as having a chiral center. The term *chiral* is derived from the Greek, *chiros* or handed, and refers to an object that cannot be superimposed on its mirror image (Fig. 11.1).

Molecules that contain a single chiral center and are nonsuperimposable mirror images of one another are described as enantiomers. Enantiomers cannot be separated using traditional separation methods such as distillation, crystallization, or chromatography on columns packed with achiral materials. Their physical properties (e.g., dielectric constant, melting point, boiling point) are also the same. However, enantiomers (as described earlier) do differ in their ability to rotate plane polarized light. Compounds that rotate light clockwise are called *dextrorotatory*; those that rotate light counterclockwise are termed *levorotatory*. Dextrorotatory compounds are

TABLE 11.1 Constitutional Isomers That Exist with Molecular Formula C_3H_8O Each with Different Bond Connectivities and Physical–Chemical Attributes

Compound	Structure	Specific Density (g/mL)	Boiling Point ($^{\circ}C$)
1-Propanol		0.804	97.8
2-Propanol		0.789	82.5
Ethyl methyl ether		0.725	10.6

Figure 11.1 Example of the differing biological activity between enantiomers.

Figure 11.2 A chiral molecule possesses at least one chiral atom in its structure. This is most often an atom of carbon with four different substituents. If all four substituents are different, then two stereoisomers (enantiomers) exist, one of which is the mirror image of the other.

designated with the (+) descriptor in their chemical names; levorotatory compounds are designated with the (−) symbol (e.g., (+)-dobutamine and (−)-dobutamine). In addition, the configuration of enantiomers may also be described in terms of its stereochemistry using the Cahn–Ingold–Prelog (CIP) convention [2]. The CIP naming system assigns a priority to each substituent on the chiral center (Fig. 11.2) and ranks atoms attached to a chiral carbon according to atomic number. Specifically, the higher the atomic number, the higher the priority. If two atoms attached to the central carbon have the same atomic number (e.g., two carbon atoms), one moves along the chain until there is a difference between the atoms; the group in which the higher atomic number atom is found closest to the chiral carbon receives the higher priority. For example, an ethyl group receives a higher priority than a methyl group. Once the various substituents have been ranked, the molecule is visualized in an orientation that places the lowest priority substituent, often a hydrogen atom, directly behind the chiral center. If the remaining substituents decrease in priority around the chiral center in a clockwise direction, the substance is described as the R (rectus) enantiomer. Alternatively, if the direction is counterclockwise, the substance is declared to be the S (sinister) enantiomer (Fig. 11.3). In this fashion, a chiral substance is typically

Figure 11.3 The stereochemical assignment for glyceraldehyde according to the Cahn–Ingold–Prelog convention. The chiral center is oriented with the lowest priority substituent (in this example hydrogen) pointing away from eye. In the case of glyceraldehyde, priority decreases in the following order: OH, -CHO, and CH₂OH. If these three substituents in decreasing order are placed clockwise, the chiral center is described as being in the R (rectus) configuration. Conversely, if the substituents result in an anticlockwise ordering, the chiral center is in the S (sinister) configuration.

described by its stereochemical descriptor (R or S), optical properties (+ or –), and chemical name (e.g., (+) (*S*)-mephénytoin).

Emil Fisher first described the significance of stereoselectivity in biological systems. In his “key and lock” hypothesis, Fisher attempted to account for the achiral nature of biological systems, where only one of the two possible enantiomers of amino acids and sugars (specifically, L-amino acids and D-sugars) make up living systems. Further refinement of the “key and lock” hypothesis led to the assumption that there existed a stereochemical relationship between the achiral protein and enantiomeric substrates (Fig. 11.4). The notion of a stereochemical influence governing the dynamic relationship between enzyme and substrate was further refined by Pauling and Delbruck, who

Figure 11.4 (a) The active enantiomer has a three-dimensional structure that allows drug moiety A to interact with binding site domain a, B to interact with b, and C to interact with c. In contrast, (b) the inactive enantiomer cannot align in a manner which allows the three sites to bind simultaneously. The difference in three-dimensional structure allows the active enantiomer to bind and elicit a biological effect, while the inactive enantiomer cannot.

proposed that the catalytic activity of an enzyme derives from the steric distortion of the substrate when it binds toward the structure of the transition state for the reaction [3].

A general theory that holds for many interactions of enantiomers with biological systems was proposed by Carl Pfeiffer who, in 1956, observed that potent chiral molecules display large differences in potency between enantiomers, whereas weakly active compounds have relatively little difference between enantiomers [4]. This observation can best be illustrated by consideration of how molecules interact with the environment (e.g., a receptor or enzyme active site). For any ligand, the possible noncovalent interactions can be separated into subsets of van der Waals, hydrogen bonding, charge transfer, and electrostatic interactions. Collectively, all these interactions types combine to produce a three-dimensional property cloud [5]. Any of these forces may predominate in a particular receptor interaction, but for molecules that possess high affinities, each force should approach maximal effect. This is only possible when the molecular envelopes around the ligand and receptor are complementary. For instance, in the case of directly acting adrenergic agonists, the Easson–Stedman hypothesis proposes a three-point attachment of the active enantiomer (–)-(R)-adrenaline to the adrenergic receptor as opposed to only a two-point attachment for (+)-(S)-adrenaline, which has a lower affinity. Thus, binding of a drug molecule to a receptor, enzyme, or other protein depends on certain structural features [6]. The active drug molecule has several points of attachment to corresponding areas within the receptor site and, in addition, for drugs with an asymmetric carbon atom require a certain spatial configuration of the functional groups for optimal binding to the receptor (Fig. 11.5). Obviously, there can be different affinities for each enantiomer in its interaction with a particular receptor or enzyme (Table 11.2). Under these conditions, the enantiomer with the highest affinity is termed the *eutomer* and the one with the lower affinity is the *distomer*. The eutomer:distomer ratio is called the *eudismic ratio*, and the logarithm of the eudismic ratio is described as the *eudismic index* [7].

In nature, the number of chiral natural molecules is very large, and they represent immense structural variability. Among these substances, an overwhelming majority

Figure 11.5 A cartoon of a receptor ligand complementary interaction using a three-point receptor model with (–)-(R)-adrenaline as a representative ligand.

TABLE 11.2 Examples of Chiral Drugs Across Various Therapeutic Classes That Exhibit Stereoselective Potencies

Therapeutic Class	Isomer Potency
<i>β-Blockers</i>	L > D
Propranolol, metoprolol, labetalol	Example: (<i>S</i>)-propranolol > (<i>R</i>)-propranolol
<i>Anesthetics</i>	L > D
Isoflurane, ketamine	Example: (<i>S</i>)-ketamine > (<i>R</i>)-ketamine
<i>Analgesics</i>	D > L
Ketoprofen, ibuprofen	Example: (<i>S</i>)-ibuprofen > (<i>R</i>)-ibuprofen
<i>Tranquilizers</i>	D > L
Oxazepam, temazepam, lorazepam	Example (<i>S</i>)-oxazepam > (<i>R</i>)-oxazepam
<i>Opiate Analgesics</i>	D > L
Methadone, pentazocine	Example: (<i>R</i>)-methadone > (<i>S</i>)-methadone
<i>Calcium Channel Blockers</i>	L > D
Verapamil, nimodipine, felodipine	Example: (<i>S</i>)-verapamil > (<i>R</i>)-verapamil
<i>Sedatives</i>	L > D
Secobarbital, hexobarbital, mephobarbital	Example: (<i>S</i>)-secobarbital > (<i>R</i>)-secobarbital
<i>Bronchodilators</i>	L > D
Albuterol, salmeterol, terbutaline	Example: (<i>S</i>)-albuterol > (<i>R</i>)-albuterol

occur in unichiral form, reflecting a single enantiomer. For example, chiral α -amino acids, and the peptides and proteins containing them, sugars and their polysaccharides, steroids, antibiotics, and many other compounds from nature are generally unichiral. A second interesting aspect of many naturally occurring chiral molecules is their homochirality. This term suggests that related chiral molecules in the same chemical class usually have the same sense of chirality. For example, with rare exceptions, α -amino acids occurring in nature consistently possess an L-configuration; similarly, monosaccharides are typically found to exist in a D-configuration. With respect to other molecules derived from natural sources, chirality is also the norm.

As mentioned above, stereoselective interactions between a ligand and receptor are observed across a wide range of pharmacological classes; this is particularly true for the vast majority of early drugs that are derived from natural sources [8]. For example, opium powder obtained from the dried juice from the unripe seed capsule of the poppy *Papaver somniferum* was recognized for its medicinal properties by ancient civilizations in Egypt and Mesopotamia. However, it was not until 1805 before the active ingredient in opium powder was isolated and purified by Friedrich Wilhelm Sertürner, a German pharmacist who named the molecule morphium after Morpheus, the Latin god of dreams. The morphine molecule is a pentacyclic tertiary amine with five chiral centers and exists as the levorotatory enantiomer [9].

Quinine is another example of a chiral drug which has some historical interest. Early civilizations of South America used the bark of the *cinchona* tree to treat fevers. At the beginning of the seventeenth century, Spanish conquerors learned of the bark's medicinal uses, and by the middle of 1600s, the extract of cinchona was being used in Europe for the treatment of malaria. In 1820, quinine, the main antimalarial ingredient from cinchona bark was isolated. The quinine molecule contains four chiral carbon centers [10] and like morphine also exists as the levorotatory enantiomer.

By the mid-twentieth century, a shift from molecules from plant origins to synthetic drugs was forming the basis of contemporary drug therapy. Interestingly, unlike the earlier molecules derived from biological sources, the vast majority of synthetic drugs introduced were racemic, and by the late 1980s, roughly a quarter of the drugs on the market were chiral and racemic [11]. Among the earliest entirely synthetic racemic drugs class was the anticonvulsant or sedative barbituric acid derivatives (e.g., phenobarbital). The significance of this class of molecule with respect to the scope of the current chapter is that the first report of the synthesis of the enantiomers of a barbituric acid and a comparison of the efficacy and toxicity for each enantiomer was released in 1927 [12]. However, the FDA did not explicitly request the inclusion of information on the enantiomer composition of chiral substances in new drug applications until 1992, when they issued their guidelines governing the development of new chiral drugs [13].

The role of stereochemistry in the pharmacology of drug action is well documented. An equally important aspect of stereoselectivity of drug action is the role chirality plays in drug metabolism and toxicity. To this end, the remainder of this chapter is divided into two sections: the role of stereoselectivity in drug metabolism and the implications of stereoselectivity in drug toxicity.

11.3 STEREOSELECTIVITY IN DRUG METABOLISM

Drug metabolism represents an integral contributor to the many physiological processes that govern the dispositional fate of most therapeutic agents. In rudimentary terms, drug metabolism can be described as the biological transformation of lipophilic, nonpolar molecules (e.g., drugs) to more hydrophilic, polar molecules (e.g., metabolites), which are in turn more readily eliminated from the body. The chemical routes by which drugs are susceptible to drug-metabolizing enzymes are large and varied. In fact, one particular feature that distinguishes drug-metabolizing enzymes from other “classical” enzymes is the wide variety of reactions that these enzymes can carry out. In 1959, Williams classified the drug metabolism reactions that are catalyzed by this group of enzymes into two general phases: phase I and phase II reactions [14]. Phase I (oxidative) reactions typically involve the addition or removal of a functional group to increase a compounds polarity, and phase II (conjugative) reactions involve the addition of a hydrophilic moiety to the lipophilic molecule to make it more water soluble.

As with all enzyme-mediated reactions, drug-metabolizing enzymes are capable of accelerating a chemical reaction as compared to the rate of reactions carried out on a laboratory bench top under the mild conditions of aqueous solution, room temperature, and neutral pH. In terms of the concepts describing chemical thermodynamics, enzyme catalysis is essentially a lowering of the free energy function (G) associated with a given chemical reaction [5]. A change in free energy for a reaction, ΔG , determines if a reaction is spontaneous or not. Equilibrium conditions are governed by the standard free energy change ΔG° , and there are several means by which enzymes are able to decrease activation energy. The catalytic power and specificity of an enzyme is a reflection of the steric and electrostatic features associated with the enzyme active site [6]. The most important of these involves the enzyme initially binding the substrate and allows the molecule to exist in close proximity to the catalytic groups found within the active enzyme complex [15]. When the substrate is bound to the enzyme, the enzyme

changes conformation and forces the substrate into a strained or distorted structure that mimics the reaction transition state [3], thus reducing the energy of activation. In this conformation, the substrate is forced into a reactive state and, due to the loss of the substrate's translational and rotational entropy, is shifted toward the total activation energy [16].

Although small in relative numbers, drug-metabolizing enzymes are able to catalyze a large variety of reactions because of their structural and chemical diversity. However, similar to receptor interactions, biotransformation reactions carried out by the drug-metabolizing enzymes also exhibit a wide degree of stereoselectivity [17,18].

Stereoselective drug metabolism can be further refined in terms of substrate and product stereoselectivity. Substrate stereoselectivity applies to a condition in which two enantiomers (or other optical isomers) are metabolized at different rates, without the introduction of a new asymmetric center. When a (new) chiral center is formed during biotransformation, and the resulting products are formed at different rates (selective generation of stereoisomers from a single substrate), this is called *product stereoselectivity*. Reactions are defined as stereospecific when they are completely stereoselective, that is, when only one of the stereoisomers participates in the reaction while the other does not.

11.3.1 Substrate Stereoselective Metabolism

As mentioned earlier in the chapter, the cornerstone of chiral protein–ligand interactions is based on the fact that proteins are chiral in nature, as they are exclusively composed of L-amino acids. In this light, all enzyme reactions are, in theory, stereoselective, and thus, interactions with other chiral molecules have the potential to reflect stereoselectivity. As a consequence of, mechanisms of stereoselective drug metabolism can occur at the substrate binding step and/or at the catalytic step, which may result in different affinities and/or reactivity's of the two enantiomers. With respect to the drug metabolism, the recognition of enantiomeric substrates is assessed in terms of substrate enantioselectivity (i.e., the differential metabolism of two enantiomers under identical conditions). This condition is in contrast with product enantioselectivity, which describes the differential formation of two enantiomeric metabolites from a single prochiral substrate.

In the case of substrate stereoselectivity, the two enantiomers are metabolized either at different rates or by different metabolic routes leading to the differential disposition of one enantiomer compared to the other. The differences in metabolism of the stereoisomers of chiral drugs are a result of different spatial orientations between the two enantiomers and the manner in which they interact with the active site of the enzyme. If one enantiomer aligns in a more productive orientation of functional groups within a particular enzyme active site than the other, the rate of reaction for a particular metabolite will be enantioselective. For example, the oxidative metabolism of the racemic anticonvulsant drug, mephenytoin, is enantioselective [19]. In this instance, the (*S*)-enantiomer is metabolized by oxidation to 4-hydroxymephenytoin, a reaction catalyzed by the polymorphically expressed enzyme cytochrome P450 2C19 (CYP2C19) [20]. In contrast, (*R*)-mephenytoin is metabolized principally by N-dealkylation to phenylethylhydantoin by several other cytochrome P450 (CYP) enzymes [21]. *In vivo* oxidation of (*S*)-mephenytoin is more rapid than N-demethylation of (*R*)-mephenytoin, and as a consequence, there are large differences between the pharmacokinetics of

(*R*)- and (*S*)-mephenytoin [22]. A second example of stereoselective drug oxidation associated with CYP2C19 is found with the metabolism of omeprazole. Interestingly, unlike the enantioselective oxidation observed between (*R*)- and (*S*)-mephenytoin, CYP2C19 is able to bind and oxidize both the enantiomers of omeprazole. However, in this instance, the enzyme favors the 5-hydroxylation of (*R*)-omeprazole and the 5-*O*-demethylation of the (*S*)-omeprazole benimidazole group [23,24].

CYP2C19 is not the only P450 isoform involved in stereoselective substrate metabolism. For instance, (*S*)-methadone is preferentially metabolized by CYP2B6 compared to (*R*)-methadone [25]. In the case of CYP3A4, the enzyme is capable of carrying out N-dealkylation reactions on both (–) and (+)-cisapride; however, the enzyme selectively oxidizes (+)-cisapride to form 4-fluoro-2-hydroxycisapride, while the (–)-enantiomer is metabolized to yield 3-fluoro-4-hydroxycisapride [26]. In fact, stereoselective drug oxidation is observed for select substrates for all known drug-metabolizing P450 enzymes.

As stated above, stereoselectivity in drug metabolism is a manifestation of the interaction between the chiral drug and the achiral environment, which makes up the drug-metabolizing enzyme active site and, as a consequence, is not limited to CYP-mediated oxidation reactions. For example, propranolol, a nonselective β -adrenergic blocker used as a racemic mixture in the treatment of hypertension, cardiac arrhythmias, and angina pectoris is cleared (~20%) by direct glucuronidation [27]. Two of the primary UDP-Glucuronosyltransferase (UGT) enzymes responsible for the conjugation of propranolol in humans are UGT1A9 and UGT1A10 [28]. Stereoselective analysis of the rates of conjugation of the enantiomers of propranolol revealed a high degree of stereoselectivity in the glucuronidation of each enantiomer. In this instance, UGT1A9 was able to glucuronidate (*S*)-propranolol much faster than (*R*)-propranolol, whereas UGT1A10 possesses the opposite enantiomeric preference [29]. In light of the fact that the expression of UGT1A10 is limited to intestine [30] compared to UGT1A9, which is expressed in liver [31], experiments that examined the tissue selectivity of propranolol glucuronidation revealed that human liver microsomes glucuronidated (*S*)-propranolol faster than (*R*)-propranolol, while human intestine microsomes glucuronidated (*R*)-propranolol faster than (*S*)-propranolol [29].

In fact, it is hardly surprising that there are examples of stereoselective substrate recognition observed for majority of the drug metabolism enzyme systems: sulfotransferases (e.g., salbutamol) [32], esterases (e.g., pyrethroid insecticides) [33], glutathione transferases (e.g., 4-hydroxynonenal) [34], flavin-containing monooxygenases (FMOs) (e.g., sulindac) [35].

11.3.2 Metabolite Stereoselectivity

While the stereoselectivity associated with the favored recognition of one enantiomer over its antipode by a particular enzyme is impressive, perhaps a more subtle example of stereoselective drug metabolism is seen with the oxidation of a prochiral substrate. The term *prochirality* also applies to an achiral molecule or entity that contains a trigonal system, which can be made chiral by the replacement of an existing atom (or achiral group) by a different one [36]. In this instance, the observed difference in recognition or the rates of formation of two enantiomers derived from a prochiral substrate is a direct reflection of the topography of the active site of the enzyme since

the architecture of the active site is the only physical feature in the system that can elicit this effect.

In light of the topographical constraints an enzyme active site may exert onto a chiral drug molecule it is possible that metabolism of an achiral compound can introduce a new center of chirality. There are several types of enzymatic (reductive and oxidative) pathways of drug metabolism that can produce new chiral centers in substrate molecules (Fig. 11.6). These reactions include (i) ketone reduction leading to a secondary alcohol; (ii) reduction of a carbon–carbon double bond; (iii) oxidation of a sulfide to a chiral, configurationally stable sulfoxide; (iv) oxidation of a tertiary amine to an *N*-oxide; and (v) oxidation of an enantiotopic or a prochiral moiety leading to a chiral metabolite.

11.3.2.1 Ketone Reduction Leading to a Secondary Alcohol. Stereoselective reduction of a ketone is reflected in the metabolism of the achiral neuroleptic drug, haloperidol. The major pathway of haloperidol metabolism in humans is reduction of the ketone to a secondary alcohol [37,38]. This enzyme reaction is catalyzed by cytosolic ketone reductases and is stereospecific, producing primarily the (S)-enantiomer of haloperidol [39,40]. The mechanism of chiral metabolite formation by carbonyl-reducing enzymes is via two-electron reduction, involving hydride transfer from the cofactor to the carbonyl carbon, which is facilitated by general acid chemistry through a catalytic tetrad (Tyr, Asp, Lys, and His), which forms an oxyanion binding site with the nicotinamide ring of the cofactor [41]. In this reaction, nonsymmetrical ketones generate chiral centers on reduction to alcohols, where the stereoselectivity of carbonyl-reductase-catalyzed ketone reduction is dependent on the steric situation of the substrate, and may be predicted with “Prelog’s rule” [42]. Prelog’s rule describes the reduction of ketone to yield optically active secondary alcohols. In this instance, the chirality of an alcohol arising from nucleophilic addition to a ketone depends on which prochiral face

Figure 11.6 Selected examples of various reductive and oxidative metabolism reactions that are capable of introducing new centers of chirality in molecules.

accepts the nucleophile and the sequence priority of the nucleophile relative to other substituents of the carbonyl function [43]. In hydride transfer reactions, the hydride nucleophile will always be the lowest priority group; thus, the *re* face addition of the hydride to a ketone will always generate an (S)-configuration alcohol. The stereoselective product specificity can be represented using a simple scheme (Fig. 11.7). In this scheme, the S (small) and L (large) represent the relative bulk of the groups adjacent to the carbonyl.

11.3.2.2 Chiral Reduction of a Carbon–Carbon Double Bond. Reduction is defined in chemistry terms as loss of oxygen, gain of hydrogen, or gain of electrons. With respect to a molecule's double bond, reactions tend to be addition reactions, where the unsaturated carbon atoms become saturated. When the reaction involves the addition of hydrogen to a carbon–carbon double bond, this process is called *hydrogenation*. The overall effect of such an addition is the reductive removal of the double bond functional group, and in most cases, the stereoselectivity of the reaction is not controlled. In contrast, reductions of double bonds carried out in biological systems are typically stereoselective in nature [44]. An example of stereoselective reduction of a drug which contains a carbon–carbon double bond is reflected in the metabolism of tirilazad. Tirilazad, a 21-aminosteroid, is a potent inhibitor of membrane lipid peroxidation *in vitro* [45] and has shown efficacy in the clinical treatment of subarachnoid hemorrhage [46]. From *in vitro* experiments, the major pathway of tirilazad metabolism was determined to be mediated by CYP3A [47]. The role of CYP3A was confirmed on coadministration of tirilazad with ketoconazole, a specific CYP3A inhibitor, which dramatically reduced the clearance of tirilazad

Figure 11.7 Schematic of steric constraints associated with carbonyl reduction reactions. Inset: The reduction of haloperidol to (*S*)-reduced haloperidol.

in vivo [48]. However, despite the contribution of CYP3A to drug clearance, the major metabolite of tirilazad found in circulation was formed via reduction [49]. In human liver microsomes, 5 α -reductase was found to catalyze the formation of the reduced metabolite [50]. Under these conditions, 5 α -reductase catalyze the bisubstrate reaction between tirilazad and NADPH to stereoselectively produce the 5 α -dihydrotirilazad metabolite and NADP⁺ [51]. Mechanistic studies have demonstrated that the 4-ene steroid 5 α -reductase reaction proceeds through the direct regioselective transfer of protons from NADPH to steroid in a random bireactant process [52].

11.3.2.3 Oxidation of a Sulfide to a Chiral Sulfoxide. Thioethers are a common chemical moiety for several drug molecules across a range of therapeutic classes. These molecules can exist as either diaryl-dialkyl or arylalkylthioethers (Fig. 11.8), and because the sulfur group can exist in a variety of oxidation states (including -2, +4, and +6), it is not surprising that thioethers are susceptible to single oxidation reactions leading to a sulfoxide formation. The most common chemical oxidation protocols utilize peroxides or peracids as oxidants in solution and proceed with no stereochemical preference generating racemic sulfoxides.

In contrast, sulfide oxidation via drug-metabolizing enzymes can proceed in a stereoselective manner because of the potential constraints associated with active site topography associated with these reactions. Perhaps the greatest influence of active site topography on the stereoselectivity of drug oxidation is observed with FMO oxidation reactions [53,54]. In the 1980s, Walsh and coworkers examined the stereochemistry of sulfoxidation of ethyl *p*-tolyl sulfide by hepatic microsomal FMO and found that the enzyme catalyzed formation of the (R)-enantiomer of ethyl *p*-tolyl sulfoxide in great enantiomeric excess [55,56]. In this fashion, unlike the ketone reductase mechanism, the topography of the enzyme active site not the substrate dictates the final chirality

Figure 11.8 Examples of drug molecules that exist as either diaryl-dialkyl or arylalkyl-thioethers.

of the product, as the enantiotopic electron pairs on the sulfur atom of an asymmetrically substituted sulfide are equivalent [57]. However, in the chiral environment of the enzyme active site, the electron pairs are not equivalent and stereoselective sulfoxidation can occur. For example, albendazole is a broad-spectrum anthelmintic agent used to treat tropical parasitic disease [58]. Albendazole contains a sulfur group that is stereoselectively oxidized by FMO to form an active metabolite, (*S*)-sulfoxide albendazole [59].

11.3.2.4 Oxidation of a Tertiary Amine to an *N*-Oxide. The oxidation of drugs possessing a tertiary amine frequently yields *N*-oxides as major metabolic end products [60,61]. In this circumstance, a tricoordinate nitrogen atom with three different substituents is not chiral due to rapid inversion of the two possible antipodes via a planar transition state [62]; however, the corresponding quaternary *N*-oxide is chiral. Thus, the metabolic formation of an *N*-oxide of this type may show product stereoselectivity or stereospecificity, which may have implications if the metabolite is either pharmacologically or toxicologically active and such activity is selective for one enantiomer. Many of the chiral *N*-oxide metabolites observed are the product of FMO oxidation, where the sp^3 -hybridized electron-rich nitrogen atom serves as a suitable reactant toward the weak oxidation potential of the 4 α -hydroxyflavin of the enzyme [63].

The subtlety of the stereoselectivity of *N*-oxide formation by FMOs is a consequence of the enzyme active site and the mechanism of oxidation by the FMO enzyme. For FMO enzymes, in the first step of the catalytic cycle, FAD undergoes two-electron reduction by NADPH [64]. Chemistry of NADPH requires that reduction of the flavin cofactor is facilitated through a hydride transfer from the C4 atom of the nicotinamide ring to the flavin N5 atom [65]. The reduced flavin reacts rapidly with molecular oxygen to form the stable peroxyflavin intermediate, which is able to wait for a suitable nucleophile (in this case, a tertiary amine) with which to react [66]. Stabilization of the intermediate requires the presence of $NADP^+$ [67], which remains tightly bound to the enzyme throughout the catalytic cycle. It has been proposed through computer simulation of the FMO active site that $NADP^+$ is able to shield the enzyme active site and can provide a possible H-bonding environment for stereospecific oxidations [68]. Finally, the binding of oxygen is followed by the nucleophilic attack by the tertiary amines on the peroxyflavin, which results in one atom of molecular oxygen being transferred to the substrate.

One molecule that undergoes stereospecific *N*-oxide formation is nicotine. In humans, there are large interindividual differences in nicotine disposition, and it has been proposed that genetic polymorphisms in nicotine metabolism may be a major determinant of an individual's smoking behavior [69]. Hepatic cytochrome P450 2A6 (CYP2A6) catalyses the major route of nicotine metabolism: oxidation to cotinine, followed by hydroxylation to *trans*-3-hydroxycotinine [70]. Nicotine also undergoes *N*-oxidation to form *trans*-*N*-1-oxide a reaction catalyzed by hepatic flavin-containing monooxygenase form 3 (FMO3) [71].

11.3.2.5 Oxidation of an Enantiotopic Moiety Leading to a Chiral Metabolite. There are several examples of achiral molecules that on enzyme metabolism yield a chiral product. Perhaps the most cited achiral drug that undergoes stereospecific metabolite formation is observed with the epileptic drug, phenytoin. Phenytoin (5,5-diphenylhydantoin, Dilantin[®]) is a hydantoin anticonvulsant that is widely used for the

treatment of complex partial seizures, secondarily generalized tonic–clonic seizures and acute seizures [72]. The primary metabolic pathway for phenytoin is aromatic oxidation to form 5-(4-hydroxyphenyl)-5-phenylhydantoin (*p*-HPPH) [73]. From *in vitro* studies, it has been established that the major enzyme responsible for phenytoin metabolism is CYP2C9 [74], with a minor contribution arising from CYP2C19 [75]. For the CYP2C9-mediated pathway, ~95% of the *p*-HPPH formed by this enzyme results in the (S)-configuration of the metabolite [76]. Interestingly, the second enzyme, CYP2C19, also oxidizes phenytoin to the phenolic metabolite; however, in this reaction, the (R)-*p*-HPPH is primarily formed [77]. The dominance of CYP2C9 stereoselective metabolism of phenytoin is evident from the urinary (S)/(R) ratio of *p*-HPPH, which is about 24:1 [78].

A second example of an enantiotopic drug being metabolized to a chiral product is observed with the 4-hydroxylation of the antihypertensive debrisoquine, a reaction that is principally catalyzed by CYP2D6 [79]. In humans, CYP2D6 exhibits a genetic polymorphism [80] such that for extensive metabolizers, more than 99% of the 4-hydroxydebrisoquine metabolite possesses the (S)-configuration [81]. In contrast, poor metabolizers of debrisoquine not only have a severely impaired capacity to form 4-hydroxydebrisoquine but also show less stereoselectivity, with 5–36% of the 4-hydroxydebrisoquine possessing (R)-configuration [82,83].

11.3.3 Chiral Inversion

As previously mentioned, enantiomers may have similar or different pharmacological effects, and these effects may be related to stereoselective pharmacokinetics or pharmacodynamics. In the latter case, the terms *eutomer* for the more potent isomer and *distomer* for the less potent one are applied. However, independent of the qualitative or quantitative differences in pharmacological activity between isomers, the definition of a racemate being a 50:50 mixture of each isomer remains constant. While this is typically the case, there are some circumstances where there is an interconversion (chiral inversion) between one enantiomer and the other [84].

There are two kinds of drug chiral inversion: unidirectional and bidirectional inversion.

Bidirectional chiral inversion or racemization of enantiomers is thermodynamic in nature and is governed via an equilibrium process. An example of racemization of enantiomers is observed with 3-hydroxy-benzodiazepines (e.g., oxazepam) in which the (R)- and (S)-enantiomers are able to racemize in aqueous solutions [85]. In contrast, enzyme-mediated inversion is not a thermodynamic phenomena but rather occurs through an enzyme-mediated process where there is stereoselective recognition of one enantiomer over another, which results in a unidirectional racemization.

Unidirectional inversion from (R)- to (S)-configuration is the most common feature for 2-arylpropionate nonsteroidal anti-inflammatory drugs (NSAIDs) exemplified by the common over-the-counter (OTC) analgesic, ibuprofen [86,87]. This is of particular importance, given that for this class of molecule, the (S)-enantiomer is the more active enantiomer (i.e., has an analgesic and anti-inflammatory effects). In fact, (S)-ibuprofen is over 100 times more potent as an inhibitor of cyclooxygenase I than (R)-ibuprofen [88].

The inversion of a chiral center is, from a chemical reaction perspective, an energetically demanding reaction where a number of possible reaction sequences can be

hypothesized. From a first principal perspective, C2 (i.e., the carbon atom adjacent to the carboxyl group) of ibuprofen must become planar for epimerization to occur. For ibuprofen as well as other arylpropionic acids, this planar structure can be achieved *via* β -oxidation to form a dibond between C2 and C3, or alternatively, by carbanion formation at C2 resulting from proton dissociation. In this fashion, formation of a planar intermediate is similar to the mechanism of acyl-CoA synthetases formation of acyl-thioesters from fatty acids in the presence of ATP, CoA, and Mg^{2+} , as part of a critical step in fatty acid metabolism.

The stereoselective introduction of CoA into (*R*)-ibuprofen to form the thioester bond increases the acidity of the proton on the C2. The dissociation of the α -methine proton of (*R*)-ibuprofen CoA ester is facilitated by both the aromatic ring and the thioester bond during racemization step. This step of reaction does not occur spontaneously and requires the presence of an epimerase [89], as the predicted pK_a value of the α -methine is greater than 10 and therefore is incapable of dissociation under physiological pH conditions [90]. On proton abstraction, an unstable carbanion intermediate is formed, which undergoes tautomerism to form a double bond between C2 and C1. The planar structure is now able to accept a solvent proton, from either the upper or the lower side, in a nonstereoselective manner to yield (*S*)-ibuprofen CoA ester. The last step of the unidirectional inversion of (*R*)-ibuprofen is simply the hydrolysis of CoA ester by the nonstereoselective catalysis of acyl-CoA thioesterase [91]. The complete scheme of the unidirectional inversion of (*R*)-ibuprofen is described in Fig. 11.9.

11.3.4 Stereoselective Inhibition of Drug-Metabolizing Enzymes

The stereoselective metabolism of chiral drugs has been evaluated thoroughly in the first section of this chapter; however, the notion of stereoselective enzyme inhibition is also an important component to understanding potential liabilities associated with a particular medicine.

For many therapies, it is quite common for two or more drugs to be coadministered to a patient, and as a consequence, the patient has an increased risk for incurring an adverse drug–drug interaction (DDI) [92,93]. DDIs are often caused by one of the administered drugs inhibiting the metabolism of the second drug. If the drug whose metabolism is inhibited has a narrow therapeutic index, the increase in systemic exposure can lead to adverse reactions.

Of the various drug-metabolizing enzymes, by far the CYP enzymes are responsible for the clearance of drugs in humans [94]. As a consequence, CYP enzymes are particularly prone to inhibition because of their broad substrate specificity [95], which makes them amenable to competitive inhibition arising from different types of structurally diverse drugs that can be metabolized by the same enzyme.

As one would predict, a chiral drug can often inhibit P450-mediated metabolism in a stereoselective manner. For example, dramatic stereoselective inhibitory interactions have been observed between the individual enantiomers of a chiral drug and P450 enzymes [96]. The degree of stereoselective inhibitory potency of a chiral molecule toward P450 enzymes is oftentimes a reflection of the topography of the enzyme active site [97]. In fact, the restricted active site of CYP2D6 has been extensively studied and modeled in an effort to understand the important structural features and biochemical interactions of this polymorphic enzyme [98].

Figure 11.9 Proposed scheme depicting the unidirectional chiral inversion of ibuprofen.

Of all known chemical inhibitors of CYP2D6, quinidine is one of the most potent and selective inhibitors of the enzyme and is often used as a chemical inhibitor in P450 reaction phenotyping studies and DDI screening assays [99]. In contrast, quinine, the stereoisomer of quinidine, is about two orders of magnitude less potent as an inhibitor of CYP2D6 [100], which illustrates the significance that stereochemistry can play in binding and inhibition of this enzyme. Mechanistic studies suggest that in addition to different enzyme affinities, quinidine and quinine also possess distinct binding orientations within the CYP2D6 active site. For these enantiomers, quinidine produces a type I binding spectrum on binding with CYP2D6 [100], which indicates that quinidine binding causes a low to high spin state transition resulting from displacement of water as the sixth ligand to the heme iron [101]. In contrast, the binding of quinine to CYP2D6 results in a type II spectrum, which suggests that the sp^2 nitrogen in the quinoline ring, likely to be uncharged at neutral pH is complexed with the heme iron [102], which leads to a more definitive binding orientation, one which is clearly distinct from that of quinidine. Moreover, molecular modeling of the quinidine CYP2D6 interaction suggests that the enzyme bound quinidine blocks the entrance of the active pocket of CYP2D6 more effectively than quinine does [103], which provides

additional rationale for why the inhibitory activity of quinidine toward CYP2D6 is so much greater than quinine.

11.3.5 Metabolic Interactions Between Enantiomers and a Second Drug

As described previously in this chapter, a racemic drug can be thought of as mixture of two xenobiotics each displaying its own pharmacokinetic and pharmacodynamic profile. Under this circumstance, the introduction of a second drug in combination with the chiral drug has the potential to greatly complicate the situation since under these conditions, there are now effectively three possible interacting species as there is no anticipation that the second drug will interact with the two enantiomers in same way. As a consequence, the metabolism of a racemic drug may be stereoselectively modified, which can result in a variety of possible pharmacokinetic and pharmacodynamic alterations.

For example, warfarin is administered as a racemic mixture and undergoes extensive oxidative metabolism [104]. In humans, essentially all the anticoagulant effect of the drug resides with (*S*)-warfarin [105], which is primarily cleared by a single P450 enzyme, CYP2C9, to form two inactive metabolites, (*S*)-6- and (*S*)-7-hydroxywarfarin [106]. In contrast, the less potent warfarin enantiomer, (*R*)-warfarin, is metabolized by several enzymes: CYP3A4, CYP1A2, and CYP2C19 [20,107].

In clinical studies, it has been reported that total warfarin plasma concentrations were increased when the drug was coadministered with drugs such as cimetidine or sulfinpyrazone. Interestingly, while both drugs increased total warfarin plasma levels, only coadministration of sulfinpyrazone had an increase in the drug's anticoagulant effect [108]. This observation can be explained by the enantioselective metabolism of warfarin isomers. In this case, concomitant administration of warfarin with cimetidine resulted in a decreased clearance of the (*R*)-enantiomer but had no impact on the clearance of the pharmacologically active enantiomer, (*S*)-warfarin [109]. In contrast, coadministration of sulfinpyrazone and warfarin resulted in a decreased clearance of (*S*)-warfarin and, therefore, an increased effect of warfarin but relatively little impact on (*R*)-warfarin disposition [108]. Interestingly, the warfarin situation is further confounded by the fact that while (*R*)-warfarin is not metabolized by CYP2C9, it is an inhibitor of the enzyme. *In vitro* inhibition studies that examined the effect of (*R*)-warfarin on the metabolism of (*S*)-warfarin revealed that the production of both (*S*)-6- and (*S*)-7-hydroxywarfarin were competitively inhibited by (*R*)-warfarin [110]. Therefore, it is possible for a second drug, which is an inhibitor of CYP1A2 but lacks any affinity for CYP2C9, to decrease the clearance of (*R*)-warfarin as well as to a smaller extent (*S*)-warfarin through this complex interaction scheme.

11.3.6 Enantioselective Pharmacokinetics and Drug Effect

The impact of stereoselective drug metabolism and pharmacokinetics is dependent on whether individual enantiomers demonstrate qualitative and quantitative differences in pharmacological or toxicological properties. If both enantiomers demonstrate equivalent biological activity then stereoselective metabolism is likely of no practical consequence. In contrast, if enantiomers differ in their biochemical and physiological effect profile then stereoselective pharmacokinetic differences can attenuate or potentiate both therapeutic and toxicological effects. Verapamil is an excellent case

example of this later scenario and has been extensively studied over the last twenty plus years [111]. Verapamil is a racemic calcium channel antagonist for the treatment of cardiac arrhythmias, angina, and hypertension by both intravenous and oral routes of administration. Both verapamil enantiomers possess vasodilatory activity; however, the (*S*)-verapamil enantiomer has an order of magnitude more potent negative chronotropic, dromotropic, and ionotropic effects than the (*R*)-enantiomer [112,113]. Vasodilator activity is required for angina and hypertension indications while the negative tropic properties are necessary for the treatment of arrhythmia. Obfuscating the relative contribution of the individual enantiomers to the overall pharmacological effect are their complex stereoselective ADME (absorption, distribution, metabolism, and excretion) and pharmacokinetic properties. Both clearance and steady state volume of distribution were higher for (*S*)-verapamil than those for the (*R*)-enantiomer while both enantiomers demonstrated comparable terminal plasma half-life [114]. After intravenous administration, (*R*)-verapamil concentrations are approximately twofold higher than that of the (*S*)-enantiomer. Verapamil is a high hepatic extraction drug that undergoes extensive first pass metabolism further exacerbating the stereoselective pharmacokinetic profiles for the two component isomers. After oral administration, (*R*)-verapamil concentrations are approximately fourfold higher than that of the (*S*)-verapamil [115]. This administration-route-dependent enantiomer pharmacokinetic profile is believed to be the primary explanation for pharmacodynamic differences observed for racemic verapamil when dosed intravenously and orally. Verapamil is metabolized by members of several different CYP subfamilies: CYP3A, CYP1A, and CYP2C, yielding *N*-dealkyl, *O*-demethyl, and *N*-demethyl metabolites [116–118]. Results from *in vitro* human liver microsomal experiments were generally consistent with the observed *in vivo* results, which indicates a preferential metabolism of the (*S*)-enantiomer. Cytochrome P450C8 has been reported to demonstrate preferential metabolism of (*S*)-verapamil and the (*S*)-enantiomer of its *N*-demethyl metabolite norverapamil using recombinant enzyme preparations [119]. The two enantiomers of verapamil also demonstrate differences in the extent of plasma protein binding [120] and interaction with p-glycoprotein transporters [121], which may also contribute to the pharmacokinetic differences between the two enantiomers.

11.4 STEREOSELECTIVITY IN DRUG TOXICITY

Despite several decades of increased regulatory and scientific focus, there is a paucity of information in the open literature on the comparative toxicity between individual enantiomers and their respective racemate or between individual enantiomers. While there is no doubt a wealth of comparative stereoisomer toxicity data from evaluations conducted within the pharmaceutical industry, very little of this information has subsequently been formally documented in published articles. Moreover, while there are numerous examples of racemic drugs that have been withdrawn from the market because of safety concerns and adverse drug effects, the literature exploring the mechanistic basis of these adverse events and the underlying role of stereochemistry is limited and fragmented at best. Nevertheless, there are selected instances that can be extracted from the open literature that can serve as representative examples of the impact stereochemistry can have on animal and clinical safety assessment.

Comparative evaluation of the safety and efficacy of individual enantiomer compounds form the foundation of the development decision tree when considering racemic drugs versus individual enantiomers as well as the comparative evaluation of enantiomers [122].

This information has lead to the acknowledgment that the chemical and pharmaceutical characterization of potential new drug candidates are pivotal to the drug development assessment process. From a nonclinical and clinical perspective, the decision to develop a single enantiomer does not solely depend on the comparative evaluation of efficacy and safety. The stereoselective interaction of potential drugs with the enzymes, receptors, and proteins that influence a molecule's pharmacokinetic profile can often enhance or mask the inherent molecular interaction that gives rise to an enantiomer's pharmacologic and/or toxicologic effect [123].

Many of these interactions fall into two categories: (i) one enantiomer is responsible for both the therapeutic and adverse effects, while the opposing enantiomer is inactive at normal doses (e.g., albuterol) or (ii) one enantiomer is responsible for the desired pharmacological effect but its antipode is responsible for the adverse reactions (e.g., thalidomide). As noted in earlier sections, stereoselective toxicities associated native enantiomer activity, toxicities may also arise from metabolic or dispositional features, which differ between enantiomers. In this instance, stereoselective toxicity is manifested through difference in detoxification pathways for each enantiomer or in stereoselective metabolic activation leading to adverse effects.

11.4.1 Pharmacology and Toxicity Reside in a Single Enantiomer

Albuterol is a short-acting β_2 -adrenergic receptor agonist used as a bronchodilator for the relief of bronchospasm in conditions such as asthma and chronic obstructive pulmonary disease. Albuterol is the racemate of 4-[2-(*tert*-butylamino)-1-hydroxyethyl]-2-(hydroxymethyl)phenol. The bronchodilator effects are primarily attributable to the (*R*)-albuterol isomer, with little bronchodilatory activity demonstrated by the (*S*)-albuterol. The albuterol enantiomers also differ in their adverse effect profile. The (*S*)-albuterol causes hyperkalemia and proinflammatory properties, which some believe to moderate the beneficial effects of (*R*)-albuterol when administered as a racemate. The (*R*)-albuterol has also been demonstrated to cause hyperkalemia in addition to hyperglycemia, QT prolongation, and tachycardia [124,125]. Furthermore, the albuterol stereoisomers demonstrate differences in their pharmacokinetic profiles. The (*S*)-albuterol isomer demonstrates a slower systemic clearance and preferential accumulation versus therapeutically active (*R*)-enantiomer [126,127]. Originally introduced as the racemate (Proventil®), the (*R*)-albuterol enantiomer (Xopenex®) was subsequently registered in the United States on a rationale of a superior pharmacokinetic–pharmacodynamic profile.

11.4.2 One Enantiomer is Pharmacologically Active, while its Antipode is Toxic

Perhaps the most well-known case of purported stereospecific toxicity is that of thalidomide. Thalidomide, a racemic sedative–hypnotic, was prescribed to pregnant women in the late 1950s and early 1960s to ameliorate symptoms of morning sickness. The drug exhibited neurotoxicity and teratogenic effects resulting in newborns with significant physical deformities and was accordingly withdrawn in the early 1960s [128].

Figure 11.10 Stereochemical structures of (*R*)- and (*S*)-thalidomide and the interplay of chiral inversion.

Early preclinical studies in rabbits indicated that both enantiomers carried the teratogenic liability [129]. However, subsequent studies conducted in animals and human have reported that the (*R*)-thalidomide was responsible for the sedative effects [130], while the opposing (*S*)-thalidomide isomer was responsible for the teratogenic effects [131]. Unfortunately, the majority of these studies failed to fully consider the effects of *in vivo* biotransformation in the interpretation of the pharmacological and toxicological results. Multiple studies have now shown that both thalidomide isomers are unstable in solution and readily interconvert (Fig. 11.10) to form the racemic mixture in biologically relevant media [132]. It is now thought that phocomelia (birth defects) results from the inhibition of angiogenesis and vasculogenesis perhaps mediated by metabolites arising from the *in vivo* hydroxylation and/or hydrolysis of the two thalidomide enantiomers [133]. Meyring and others demonstrated that the hydroxylation of the two thalidomide enantiomers is stereospecific [134]. The chiral center of the thalidomide enantiomers is unaffected by this hydroxylation. The (*S*)-enantiomer is preferentially metabolized on the phthalimide moiety to the (*S*)-5-hydroxythalidomide. In contrast, the (*R*)-enantiomer is metabolized to (3'*R*, 5'*R*)-*trans*-5'-hydroxythalidomide, which rapidly epimerizes to yield the more stable (3'*S*, 5'*R*)-*cis* isomer further clouding the role of stereochemistry factors in the pharmacology of thalidomide [135]. Despite the long held public perception of thalidomide stereospecific toxicity, given the complexities of the solution chemical stability and biotransformation properties of the two thalidomide enantiomers, it is impossible to conclusively ascribe either the hypnotic and teratogenic effects exclusively to one or the other stereoisomer of this drug.

A second example of a case where one enantiomer is responsible for the desired pharmacological effect but its antipode is responsible for the adverse reactions seen with MK-0571. MK-0571 is a racemic leukotriene antagonist, which demonstrated protection against bronchoconstriction due to inhaled allergen challenge, exercise-induced bronchoconstriction in early clinical trials [136,137]. In safety studies in mice, MK-0571 was found to induce peroxisome proliferation precluding further clinical development. In subsequent studies, when the individual enantiomers of MK-0571 were administered to mice, a pronounced enantioselective induction of peroxisome proliferation was observed [138]. The Merck researchers demonstrated that the antiasthmatic activity resided in both (*S*)- and (*R*)-enantiomers (L-668,018; L-668,019), while the peroxisomal proliferative activity was a property of the (*S*)-enantiomer (L-668,018). Importantly, the toxicological assessment conducted by the Merck researchers ruled out pharmacokinetic and drug metabolism explanations for the observed stereoselective biological response profile in mice. In 1993, Boie and others subsequently demonstrated that the (*S*)-enantiomer preferentially activated the mouse peroxisome

proliferator-activated receptor (PPAR) versus the (R)-enantiomer [139]. On the basis of this information, the (R)-enantiomer (L-688-019; MK-0679; verlukast) was advanced to clinical evaluation contributing important data and insight to the ultimate development and registration of montelukast (Singular®).

11.4.3 Stereoselectivity in Detoxification Pathways

In a manner quite similar to proteins, the unique three-dimensional structure of DNA may also interact with certain compounds in a stereospecific manner. For most drugs, these types of interactions require a metabolic activation step, often times mediated by the CYPs [140]. Of the various types of CYP-mediated reaction products, epoxide transformations provide the opportunity for observed stereospecific carcinogenicity or mutagenicity [141]. For example, several P450 enzymes have been demonstrated to produce an electrophilic, chiral epoxide metabolite: styrene-7,8-oxide [142]. An important aspect of styrene-7,8-oxide is the difference in toxicity of the two enantiomers. In this instance, the (R)-enantiomer of styrene-7,8-oxide has been found to be four times as mutagenic to *Salmonella typhimurium* TA 100 in the Ames test than the (S)-enantiomer [143]. Moreover, in mice, the (R)-enantiomer is also more toxic to lung and liver than the (S)-enantiomer [144]. Thus, toxicity resulting from styrene exposure does not only depend on the amount of (racemic) styrene-7,8-oxide in the target tissue but also depend on the enantiomeric composition of the compound.

In vivo, detoxication of styrene-7,8-oxide has the potential to proceed via two pathways. One is via hydrolysis by microsomal epoxide hydrolase (mEH), which would result in the formation of styrene glycol. The other is conjugation of styrene-7,8-oxide with glutathione mediated by glutathione-S-transferase. Interestingly, in humans, detoxication of styrene-7,8-oxide by glutathione-S-transferase plays a minor role [145], and therefore, mEH appears to be the key enzyme in the detoxication of styrene-7,8-oxide in humans.

The catalytic mechanism of mEH is a two-step mechanism involving an initial attack of an active-site carboxylate on the oxirane followed by hydrolysis of the ester intermediate in the second step [146]. The rate-limiting step in the reaction mechanism of mEH is the hydrolysis of the intermediate [147]. Hydrolysis of the styrene-7,8-oxide enantiomers is governed in an enantioselective manner, with the (S)-enantiomer having an approximately six times higher K_m and five times higher V_{max} than the (R)-enantiomer. In this fashion, since the toxic potential (R)-styrene-7,8-oxide is higher than that of the (S)-enantiomer, stereoselective rates of mEH-catalyzed detoxication between the enantiomers is a major determinate in the risk of styrene-7,8-oxide toxicity.

11.4.4 Stereoselective Metabolic Activation Leading to Adverse Effects

Mianserin is a racemic tetracyclic antidepressant that demonstrates reduced cardiotoxicity and has a lower overdose potential than tricyclic antidepressants of its period [148]. Mianserin is an antagonist of H1, several 5HT subtypes, as well as $\alpha 1$ and $\alpha 2$ adrenergic receptors. While the overall cumulative clinical safety of mianserin has been quite favorable, there have been reports of rare but serious toxicologic side effects including agranulocytosis (~1 in 10,000), skin rashes, hepatotoxicity, and other blood dyscrasias [149–151]. On the basis of the effect on measures of serotonin receptor and noradrenaline uptake, it has been reported that (S)-mianserin is primarily

responsible for antidepressant effect [152] likely reflecting its higher affinity for the 5-HT₂ receptor [153]. The (*R*)-mianserin enantiomer has cytotoxic properties and has been reported to be toxic to human white blood cells after stereoselective metabolic activation [154]. DDI data and *in vitro* experiments indicated that CYP3A4 is primarily responsible for the metabolism of (*S*)-mianserin to 8-hydroxy-mianserin, whereas CYP3A4 and CYP2D6 have been demonstrated to preferentially *N*-demethylate (*R*)-mianserin as the primary metabolic pathway for this enantiomer [155,156]. At low drug concentrations, Riley and others demonstrated human mononuclear leukocyte cytotoxicity was more pronounced with (*R*)-mianserin than with (*S*)-mianserin and that the observed cytotoxicity exhibited a strong correlation with *N*-demethylation [154]. Riley and colleagues also demonstrated by measurement of irreversible protein binding that the generation of chemically reactive metabolites was significantly greater for the (*S*)-enantiomer than the (*R*)-enantiomer, which adds further evidence of the role of stereoselective metabolic activation as likely the underlying cause of adverse clinical effects of mianserin.

11.5 REGULATORY AND DEVELOPMENT TRENDS

As previously noted, a result of the increasing scientific body of evidence indicating the impact of molecular stereochemistry to drug safety and efficacy throughout the 1970s and 1980s, the FDA issued an initial guidance on the registration of stereoisomeric drugs in 1992 [13]. The guidance covers the chemical and biological factors that need to be described and justified if a racemic mixture is proposed for registration. In addition to pharmacological activity this guidance addresses chemical points to consider on drug substance identity purity, quality, and strength. From a biological perspective, pharmacology, toxicology, and ADME and pharmacokinetic properties must also be adequately characterized.

The increased burden of scientific and regulatory characterization of two or more molecular entities for racemic drugs as well as significant advances in stereospecific synthesis [157], preparative scale resolution of chiral entities [158], and quantitative analysis methodologies [159] have resulted in single enantiomers or achiral drugs as the primary focus of drug development efforts over the last 20 years. In the last reported survey [11] of worldwide registrations of new molecular (chemical) entities (NMEs) over the period of 1991–2002, only 14% represented racemic mixtures, 42% were achiral molecules, and 44% were single enantiomers [160,161]. In addition to these trends, there has been a pattern of converting registered racemic drugs to single-enantiomer products [162]. One of the most publicly visible examples of this strategy is the switch of racemic omeprazole (Prilosec®), a proton pump inhibitor, to (*S*)-(–)-omeprazole (Nexium®) for gastroesophageal acid reflux (GERD) and gastric and duodenal ulcers [163].

11.6 CONCLUSION

Since the discovery of chirality by Pasteur, stereochemistry has emerged as one of the most challenging and important areas of research within the discipline of pharmaceutical sciences. Stereochemistry embraces a broad variety of closely intertwined

static and dynamic aspects that are all related to the three-dimensional structure of molecules and how they relate to their achiral environment. The few examples highlighted in this chapter are hoped to reflect both the significance of chirality and the fundamental role that dynamic stereochemistry plays in the drug discovery/development continuum. Evaluation of chiral compounds must take into account three-dimensional structure–activity relationships beyond receptor–ligand interactions. In this fashion, the principles of stereodynamic chemistry of chiral compounds are discussed in terms of the complexity surrounding the toxicological and dispositional features associated with chiral molecules. The stereoselective metabolism of the chiral drugs is an interesting and a demanding field. It is anticipated that the increased knowledge of the stereoselective metabolism, as it pertains to enantioselective toxicity and carcinogenesis of the chiral molecules may be useful for the safer treatment of diseases.

12.1 SUMMARY

Drug disposition is a complex process culminating from the interplay of numerous drug-metabolizing enzymes, drug transport proteins, serum-binding proteins, and transcription factors and is affected by multiple environmental and endogenous factors. Knowledge (and applications resulting from the knowledge) about the factors that affect exposure can enable more safe and effective drug dosing. Genetic variations in drug-metabolizing enzymes (including the cytochrome P450s, glucuronosyltransferases, and sulfotransferases) and the drug transport proteins affect the function of these proteins and thereby contribute toward variability in drug disposition. Our knowledge of these functional genetic variants and the tools to interrogate them are well developed. These tools have found utility in drug development within the pharmaceutical industry, and for limited applications, making clinical treatment decisions. This chapter discusses the genetic variations in drug-metabolizing enzymes and transporters and their relevance for clinical pharmacokinetics.

12.2 INTRODUCTION

Drug disposition is a complex process affected by many intrinsic and extrinsic factors including age, body mass, renal and liver function, concomitant medication, and dietary intake. This chapter discusses how an additional intrinsic factor, genetics, affects drug absorption, distribution, metabolism, and excretion (ADME).

The concept of a heritable component to drug disposition was postulated over 100 years ago, long before Friedrich Vogel coined the term *pharmacogenetics* and defined it as the “study of the role of genetics in drug response” [1]. The early years of pharmacogenetics witnessed the identification of several, now well characterized, genetic associations with drug response, a few seminal examples of which are reported below:

1956 Succinylcholine was introduced as a muscle relaxant in the early 1950s. Soon after, it was noticed that some patients experienced much longer than the expected duration of action (h compared to min) and required mechanical ventilators for support. In the mid-1950s, Werner Kalow described an atypical cholinesterase with significantly decreased affinity for succinylcholine and showed the trait to be heritable [2,3]. Since that early seminal discovery, multiple genetic polymorphisms within cholinesterase have been identified and associated with response to multiple drugs ([4] and references therein).

1950s Isoniazid was introduced as an extremely effective treatment of tuberculosis in the early 1950s but was associated with peripheral nerve damage in a subset of individuals. Larger studies conducted to determine the cause of this toxicity led to the observation of a bimodal population distribution of isoniazid plasma levels following a standard dose of the drug and an association between the amount excreted unchanged and toxicity. Familial studies revealed that the half-life of isoniazid was an inherited trait and ultimately led to the identification of *N*-acetyltransferase (NAT) polymorphisms affecting acetylation phenotype [5–9].

1970s Adverse events in some subjects exposed to the antihypertensive drug debrisoquine or the antiarrhythmic drug sparteine were attributed to a deficiency in metabolic ability. This observation led to the characterization of an inherited, autosomal recessive trait and ultimately to the identification of CYP2D6 genetic variants ([10,11] and references therein).

As apparent from the examples above, sequence variations in the genes encoding drug-metabolizing enzymes can have a major effect on drug disposition; in recent years, similar observations have been made for genetic variants in drug transport proteins or transcription factors associated with drug-metabolizing enzymes or drug transporter genes. Such sequence variations include single nucleotide polymorphisms (SNPs), indels (short insertions or deletions), and copy number variations (CNVs; large deletions or duplications). Understanding the functional genetic variability in enzymes or transporters related to drug disposition is critical for the safe and effective use of drugs.

Since the early studies described above, the progress in this field has continued at a rapid pace—the genetic contributors to drug disposition are well studied and understood, for the most part. In the last 30 years or so, the drug-metabolizing enzymes have been cloned and genetic variants characterized; similarly, the last 10

years or so have seen much progress in the understanding and characterization of drug transporters.

Over 170 gene products are identified to have a role in drug disposition, and more than half of these are known to be polymorphic [12]. A systematic assessment of the literature showed that 59% of the drugs cited in adverse drug reaction (ADR) literature are metabolized by at least one enzyme, which is polymorphic and known to have an allele resulting in a poor metabolizer (PM) phenotype, whereas only 22% of randomly selected drugs sold in the United States and 7% of randomly selected top-selling US drugs are metabolized by enzymes with such polymorphic variability [13]. Approximately 10% of drugs approved by the US FDA between 1945 and 2005 contain pharmacogenomic information within the label, and a significant portion of these are drug disposition related [14]. In most cases, the drug labels provide pharmacogenetic (PG) information without specific recommendations or specific actions for individuals within particular genetic subgroups. An exception to this is the drug thioridazine, which is contraindicated in particular subsets of individuals, including one which is genetically identifiable (however, this may be of limited utility, given the low importance of thioridazine in routine medical practice).

Drug-metabolizing enzymes categorized by the US FDA as “valid genomic biomarkers in the context of approved drug labels” are listed in Table 12.1. These valid biomarkers are well characterized in terms of genotype–phenotype associations and have a high level of clinical validation attached to them. Other CYPs and drug transport proteins that have not attained this burden of proof yet are referred to as *exploratory* biomarkers. Only by including these exploratory biomarkers in routine PG-PK (pharmacogenetic-pharmacokinetic) analyses and generating data on genotype–phenotype correlations can they ultimately transition to “known valid” biomarker status.

PG information pertaining to drug pharmacokinetics is routinely generated by most pharmaceutical companies during the drug development process (in phase I–III clinical trials) in attempts to better understand the pathways for disposition of the compound, understand the basis of interindividual variability, and use the information for improving population PK models. After a drug is marketed, larger PG studies can be carried out given the availability of a large population of drug-exposed individuals for study.

TABLE 12.1 Valid Genomic Biomarkers in the Context of Approved Drug Labels

Context-Specific Biomarker	Prototypic Drug Associated with the Label Information Defining the Biomarker Context
CYP2C19 variants	Clopidogrel, voriconazole, prasugrel
CYP2C9 variants	Celecoxib, warfarin
CYP2D6 variants	Atomoxetine, fluoxetine HCl, codeine sulfate
DPD deficiency	Capecitabine
NAT variants	Rifampin, isoniazid, pyrazinamide
TPMT variants	Azathioprine
UGT1A1 variants	Irinotecan, nilotinib

Abbreviations: DPD, dihydropyrimidine dehydrogenase; TPMT, thiopurine methyltransferase.

12.3 ASSESSING GENETIC VARIANTS IN ADME-RELATED GENES

Historically, the search for PG-PK associations has been performed with a candidate gene approach, wherein polymorphisms within one or a few genes are assessed for their contribution toward observed variability in the measured PK parameters of a drug. More recently, high throughput and high multiplex, microarray-based technologies have become available, whereby multiple SNPs in multiple genes can be assessed simultaneously [15,16]. Such ADME panels allow for a comprehensive and simultaneous analysis of the known genes (and SNPs) for assessing PG-related PK variability for a drug and have already yielded interesting and clinically significant associations for drugs including warfarin and clopidogrel [17,18].

12.4 NOMENCLATURE OF ALLELIC VARIANTS—STAR NOMENCLATURE

The cloning and characterization of multiple highly homologous genes encoding the drug-metabolizing enzymes and transporters necessitated the development and adoption of systematic, controlled nomenclature systems for the superfamilies of CYPs, UDP-glucuronosyltransferases (UGTs), sulfotransferases (SULTs), NATs, and drug transporters [19–28]. Similarly, increased knowledge about genetic variations necessitated the development of a nomenclature system for allelic variants of individual genes. Genetic variants within the drug-metabolizing enzymes and drug transporters are classified by the star nomenclature. The star nomenclature has been adopted by scientists as a system to organize, annotate, and, most importantly, standardize the global explosion of genetic information [29]. In the star nomenclature system, *1 is designated the reference allele against which all other sequences are compared. The *1 designation is typically given to the first sequenced clone of the gene, and subsequent unique numbers are assigned to novel functional alleles. The tremendous explosion of identified sequence polymorphisms in the postgenome era, resulting from improvements in sequencing technologies, are bringing to the forefront some of the limitations of the star nomenclature system to handle this immense wealth of data; there are ongoing efforts to organize the star nomenclature system for current practice to maximize utility [30].

12.5 CYTOCHROME P450s

The cytochrome P450s are a superfamily of drug-metabolizing enzymes, which catalyze the majority of phase I drug-metabolizing activity in humans. On the basis of amino acid sequence homology, the human CYPs comprise 18 families (>40% sequence identity) and 44 subfamilies (>55% sequence identity). Completion of sequencing of the human genome provided confirmation of the presence of 57 CYP genes and 58 pseudogenes (<http://drnelson.uthsc.edu/CytochromeP450.html>; [23]). The CYPs in families 1–3 are responsible for approximately 70–80% of all phase I drug metabolism activity of clinically used drugs, whereas the CYP enzymes in other families are primarily involved in metabolism of endogenous compounds such as fatty acids, steroids, and bile acids. This section focuses on the CYPs relevant to drug metabolism.

The drug-metabolizing CYPs are a highly polymorphic group of enzymes. A comprehensive database of CYP allelic variants with links to the primary literature is maintained at <http://www.cypalleles.ki.se/>. The major relevant CYP enzymes are discussed below in order of their PG clinical relevance, and the reader is referred to <http://www.cypalleles.ki.se/> for more information on polymorphisms within these or other CYPs.

12.5.1 CYP2

The human CYP2 family is a major contributor toward drug disposition, and the various subfamilies and members comprising this family (in order of PG importance) are discussed below.

12.5.1.1 CYP2D. The human CYP2D family comprises three genes, *CYP2D6*, *CYP2D7*, and *CYP2D8*. *CYP2D7* and *CYP2D8* are pseudogenes, but *CYP2D6* is an extremely well-characterized gene and an important enzyme for drug metabolism. CYP2D6 metabolizes many commonly prescribed drugs including codeine, dextromethorphan, tamoxifen, and most tricyclic antidepressants. Of the CYPs, *CYP2D6* genomic information is the most frequently mentioned in drug labels. CYP2D6 is highly polymorphic with 78 alleles characterized to date (<http://www.cypalleles.ki.se/cyp2d6.htm>). Some of these variants result in complete lack of CYP2D6 activity, whereas others result in reduced enzymatic activity (and in certain cases, the reduction in activity is substrate specific). Genetic polymorphisms within CYP2D6 have been well characterized for their contribution toward the interindividual variability observed in the PK of CYP2D6 substrates, and clinically relevant (based on frequency or function) CYP2D6 alleles are shown in Table 12.2, but the reader is referred to <http://www.cypalleles.ki.se/cyp2d6.htm> and [31,32] and references therein for a comprehensive listing and description of alleles.

The combination of alleles carried by an individual determines the CYP2D6 activity contributing to drug metabolism. Multiple methods have been used to predict CYP2D6 phenotype (or activity) from genotype. One method for doing so is based on the number of fully functional, low function, and nonfunctional alleles carried by an individual, resulting in PM, IM (intermediate metabolizer), EM (extensive metabolizer), or UM

TABLE 12.2 Clinically Relevant CYP2D6 Alleles

Allele	Effect	Functional Outcome
*3	Frameshift	No activity
*4	Alteration of splice site	No activity
*5	Gene deletion	No activity
*6	Frameshift	No activity
*9	Amino acid deletion	Decreased activity
*10	Amino acid substitutions	Decreased activity
*17	Amino acid substitutions	Substrate-specific decreased activity
*29	Amino acid substitutions	Substrate-specific decreased activity
*41	Alteration of splice site	Decreased activity
*1/*2xN	Gene amplification	Increased activity

(ultrarapid metabolizer) phenotype. The number of CYP2D6 alleles and the range of activity of each of these alleles make the inference of phenotype from genotype quite challenging and, perhaps, equivocal. More recently, innovative methods have been employed to improve the accuracy of phenotype prediction from genotype [33,34]. Extensive amount of data have been generated on the metabolism of CYP2D6 substrates in the different CYP2D6 phenotype classes and are briefly discussed below. The reader is encouraged to review the references in this section for additional materials.

CYP2D6 PMs have low CYP2D6 metabolic capacity, exhibit higher maximum concentrations and AUCs of drugs metabolized primarily via the CYP2D6 route, and potentially result in safety issues (especially in drugs with narrow therapeutic indices). Also, the efficacy of prodrugs that require activation by CYP2D6 (e.g., codeine, tramadol, and tamoxifen) may be reduced in CYP2D6 PMs ([35–37] and reviewed in Ref. 38). On the basis of extensive research on the effect of *CYP2D6* polymorphisms on the metabolism of antipsychotic and antidepressant drugs, dose adjustments for both CYP2D6 PMs and UMs have been suggested [39], although these are generally not employed in the clinic and mostly not reflected in antipsychotic and antidepressant drug labeling. Individuals with CYP2D6 IM or EM phenotypes exhibit a wide and overlapping range of activity, and as such, distinguishing IM from EM may not be clinically relevant. At the other end of the activity spectrum, compared with PMs, the UMs exhibit high metabolic activity as a result of amplification of functional CYP2D6 alleles, and these individuals may not achieve therapeutic efficacy at normal doses of drugs metabolized by CYP2D6. For example, the UM phenotype is 10-fold more common in nonresponders than in responders to antidepressant therapy [40], and association is reported between maternal codeine use and CNS depression in breast-fed neonates [41,42].

Given the extensive amount of information available for CYP2D6 genotype–phenotype associations, it is of no surprise that CYP2D6 phenotype information and effect on metabolism is found in the labels for several drugs including aripiprazole, thioridazine, atomoxetine, protriptyline (http://www.fda.gov/cder/genomics/genomic_biomarkers_table.htm). Even though CYP2D6 metabolizer status is known to affect the PK of several drugs, genotyping before start of therapy is not required and is provided for informational purposes only; the one exception to this being thioridazine, which is contraindicated in CYP2D6-PMs (http://www.fda.gov/cder/genomics/genomic_biomarkers_table.htm).

As with most of the drug-metabolizing enzymes, there are interethnic differences in CYP2D6 allele frequencies (and the resulting PM/EM/UM phenotypes), making genotype selection in PG studies a critical factor [43,44].

12.5.1.2 CYP2C. The CYP2C subfamily of CYPs comprises CYP2C8, CYP2C9, CYP2C18, and CYP2C19, with CYP2C9 and CYP2C19 being the most clinically relevant members, although CYP2C8 also has a role in drug metabolism.

CYP2C9 is one of the principal CYPs contributing to the metabolism of commonly used drugs such as warfarin, phenytoin, tolbutamide, diclofenac, and celecoxib. Thirty-four alleles have been identified and characterized within the *CYP2C9* gene (<http://www.cypalleles.ki.se/cyp2c9.htm>), but *CYP2C9**2 and *CYP2C9**3 primarily cause the PM phenotype in individuals. The *CYP2C9**2 and *3 alleles both contain a point mutation resulting in a single amino acid change and decreased enzymatic activity. Association between *CYP2C9**2 or *CYP2C9**3 genotype and PK parameters of

at least 17 drugs has been reported [45]. Other impaired *CYP2C9* alleles such as *CYP2C9*6* and *CYP2C9*25* consist of a frameshift that results in absence of enzyme activity, but these alleles are rare. The importance of *CYP2C9* variability is reflected in the drug label information for celecoxib and warfarin (http://www.accessdata.fda.gov/drugsatfda_docs/label/2005/020998s018,0191bl.pdf and http://www.accessdata.fda.gov/drugsatfda_docs/label/2007/009218s1051blv2.pdf). In both cases, subjects who are *CYP2C9* PMs have decreased ability to metabolize the drugs and therefore have increased plasma levels given the same dose of the drug as *CYP2C9* EMs.

CYP2C19 is clinically important due to its role in the metabolism of commonly used drugs including proton pump inhibitors (e.g., omeprazole and lansoprazole), fluoxetine, sertraline, clopidogrel, and nelfinavir. There are currently 26 allelic variants of *CYP2C19* described and characterized. Several genetic variants result in decreased function, but the majority of PM phenotypes can be attributed to *CYP2C19*2* and *CYP2C19*3*. The *CYP2C19*2* allele contains a single point mutation that results in aberrant splicing, an altered reading frame, and a prematurely truncated protein with no activity; the *CYP2C19*3* allele contains a point mutation resulting in a premature stop codon and an inactive protein. Variability in *CYP2C19* activity is clinically relevant. For example, the AUCs of omeprazole, lansoprazole, and pantoprazole are approximately fivefold higher in *CYP2C19* PMs than in *CYP2C19* EMs, and at least for omeprazole, this PK association is further reflected by differences in efficacy—*CYP2C19* PMs have higher exposures and higher cure rates ([46,47] and references therein). The clinical relevance of genetic variability in *CYP2C19* is reflected in the drug labels for several *CYP2C19* substrates including those for clopidogrel and prasugrel. *CYP2C19* is a critical enzyme for conversion of clopidogrel to its active metabolite, and therefore, *CYP2C19* PMs have reduced levels of the active metabolite and potentially poorer outcomes with clopidogrel therapy [48–50]. Issues related to the *CYP2C19* genotype-guided usage of clopidogrel have been addressed extensively in the literature by researchers and medical practitioners [51–55].

12.5.1.3 CYP2A. The human *CYP2A* family comprises *CYP2A6*, *CYP2A7*, *CYP2A13*, and *CYP2A18P*. The functional members of this family, *CYP2A6* and *CYP2A13*, are expressed predominantly in the liver and respiratory tract, respectively. On the basis of its expression in the liver, *CYP2A6* is the primary contributor toward drug disposition in this family, and this gene has been extensively studied for its role in nicotine metabolism.

In addition to being the principal CYP involved in nicotine metabolism, *CYP2A6* is also involved in the metabolism of drugs such as coumarin, halothane, tegafur, and losigamone [56–59]. The *CYP2A6* gene is highly polymorphic, with 37 alleles, including a gene deletion and duplication, currently identified and named (<http://www.cypalleles.ki.se/cyp2a6.htm>). Inactive alleles of *CYP2A6* include *CYP2A6*2* (does not incorporate heme), *CYP2A6*4* (gene deletion), *CYP2A6*5* (unstable protein), and *CYP2A6*20* (truncated protein) [60–66]. Alleles with decreased activity include *CYP2A6*6*, **7*, **9*, **10*, **11*, **12*, **17*, and **19* [67–72]. As with other drug-metabolizing enzymes, there is considerable interethnic variability in the frequency of *CYP2A6* alleles. The combined frequencies of low activity (impaired or absent) alleles (*CYP2A6*2*, **4*, **5*, **7*, **9*, **10*, **11*, **17*, **19*, and **20*) are 9.1%, 21.9%, 42.9%, and 50.5% in white, black, Korean, and Japanese subjects, respectively [73],

and these interethnic differences in allele frequency are reflected in the interindividual and interethnic variability in the metabolism of nicotine and coumarin [64,74–76].

12.5.1.4 CYP2B. The human CYP2B subfamily comprises one functional gene, *CYP2B6*, and one pseudogene, *CYP2B7*. CYP2B6 metabolizes several drugs including efavirenz, nevirapine, bupropion, and propofol. The *CYP2B6* gene is highly polymorphic, and 29 alleles are currently defined (<http://www.cypalleles.ki.se/cyp2b6.htm>). Polymorphisms within CYP2B6 affect the activity and expression of the enzyme, resulting in variable pharmacokinetics of CYP2B6 substrates. For example, considerable interindividual variability in efavirenz levels and half-life is reported following oral administration and is consistently associated with CYP2B6 activity. CYP2B6 polymorphisms that affect enzyme activity are associated with higher plasma levels and the occurrence of CNS side effects; furthermore, the increased efavirenz exposure is associated with the development of resistance after treatment discontinuation [77–83]. Specifically, the 516G>T polymorphism (resulting in change from glutamine to histidine at amino acid position 172), which is part of multiple alleles (including *CYP2B6**6, *CYP2B6**7, and *CYP2B6**9), is associated with increased exposure to efavirenz. However, the metabolic phenotypes assigned to CYP2B6 (e.g., PM or EM) are not as clear as they are for other CYPs, and the effects of certain polymorphisms may be substrate specific [84]. In addition to the variability conferred by polymorphisms, CYP2B6 is also inducible by various drugs including phenobarbital, cyclophosphamide, rifampin, efavirenz, carbamazepine, and others [84]. Induction of CYP2B6 by nuclear receptors, constitutive androstane receptor (CAR), and pregnane X receptor (PXR) also affects the pharmacokinetics of CYP2B6 substrates and may confound genotype–phenotype studies.

12.5.2 CYP3

12.5.2.1 CYP3A. The human CYP3A subfamily comprises four members, CYP3A4, CYP3A5, CYP3A7, and CYP3A43. The developmental timing and expression patterns of the four isozymes are differentially regulated. CYP3A7 is present in the fetal liver and intestine but its expression decreases after birth; CYP3A43 is expressed at low levels throughout the body, but its contribution to drug metabolism is not well understood. CYP3A4 and CYP3A5 are the most relevant members of the subfamily for drug metabolism in adults. CYP3A4 is involved in the metabolism of approximately 50% of currently used therapeutic agents and, as such, has been extensively studied [85–87]. Interindividual variability in CYP3A activity is high. *In vivo* studies have shown 5- to 10-fold variability in the metabolism of CYP3A substrates, and *in vitro* studies show even greater variability (>30-fold) [88–91]. Furthermore, well-characterized drug interactions with CYP3A can increase the range of variability to approximately 400-fold ([92] and references therein). An early study that analyzed the existing literature and used a repeated drug administration measure to calculate the genetic versus environmental components of high CYP3A interindividual variability suggested that 70–90% of the variability in CYP3A activity was attributable to genetic factors [93]. However, the specific genetic factors or polymorphisms contributing to this variability remain elusive to date. The SNPs identified within the *CYP3A4* gene are generally of low frequency and do not account for the large variability observed. The continuous and unimodal distribution of CYP3A activity suggests that multiple

genes are involved in its regulation and that individual genetic factors can play only a small role [92]. Twenty CYP3A4 alleles have been reported and characterized. The *CYP3A4*1B* allele is the most extensively characterized of the CYP3A4 alleles and has been associated with multiple disease states but does not appear to affect the *in vivo* metabolism of endogenous compounds or drugs ([94,95] and references therein). Current weight of evidence suggests that interindividual variability in CYP3A4 activity may be more related to differential regulation than to genetic polymorphisms. Induction of CYP3A4 by a variety of compounds (including rifampicin, phenobarbital, dexamethasone, and hyperforin) is mediated via the PXR pathway and can increase the metabolism of other drugs that are CYP3A substrates, making them ineffective. For example, St. John's wort, which is a potent inducer of CYP3A, can cause therapeutic failure of cyclosporine, oral contraceptives, or HIV-protease inhibitors (also CYP3A substrates), if taken concurrently ([96–99] and references therein). Conversely, CYP3A inhibition, caused by drugs such as nitroimidazole antifungals, diltiazem, and verapamil, as well as dietary components such as grapefruit juice, can increase the exposure to CYP3A substrates taken concurrently and lead to adverse events [89,100,101].

In contrast to *CYP3A4*, *CYP3A5* is polymorphically expressed—CYP3A5 expression is detected in the livers of only 10–30% of Caucasians and Asians but in more than 50% of African-Americans [102–104]. The most common CYP3A5 allele in a number of ethnic populations is *CYP3A5*3*, in which a polymorphism creates a cryptic splice site resulting in an improperly spliced mRNA and a truncated protein [103,104]. Interestingly, the original CYP3A5 cDNA sequence came from a liver sample expressing CYP3A5, thus making it one of the few CYPs in which the *1 nomenclature is not designated to the most common allele. The clinical relevance of polymorphic expression of *CYP3A5* is complicated by the substrate overlap between CYPs 3A4 and 3A5 but is well characterized in the field of transplant pharmacogenetics where CYP3A5 polymorphisms are associated with elevated tacrolimus levels and dosing adjustments [105–107].

12.5.3 CYP1

The human CYP1 family comprises CYP1A1, CYP1A2, and CYP1B1. These enzymes have a major role in the bioactivation of procarcinogens, including polycyclic aromatic hydrocarbons, heterocyclic aromatic amines, and aminoazo dyes, and in the metabolism of estrogens, fatty acids, and xenobiotics. The CYP1 family of proteins is upregulated by environmental pollutants (including dioxins and polycyclic aromatic hydrocarbons) and certain drugs via an aromatic hydrocarbon receptor (AHR)-mediated pathway, and interindividual variability in expression is observed [108,109]. Currently, 11 CYP1A1 alleles (CYP1A1*1–*11), 16 CYP1A2 alleles (CYP1A2*1–*16), and 26 CYP1B1 alleles (CYP1B1*1–*26) have been characterized (<http://www.cypalleles.ki.se/>). To date, there are no reports of clinically relevant associations between CYP1A genetic polymorphisms and variability in drug disposition. Polymorphisms within the CYP1 family are not expected to affect drug metabolism in as appreciable a manner as interindividual variability in expression due to enzyme induction. Inducibility of these enzymes by a variety of drugs and environmental pollutants does affect their activity, potentially leading to undesirable outcomes. Induction of CYP1A in humans is highly variable, and high expression can potentially increase the risk of lung cancer in smokers because of the increased bioactivation of polycyclic aromatic hydrocarbons

[110,111]. Similarly, overexpression of CYP1B1 can result in increased conversion of steroid hormones or exogenous substances into toxic metabolites resulting in neoplastic progression (e.g., the conversion of 17 β -estradiol to 4-OHE₂ or activation of procarcinogens such as polycyclic aromatic hydrocarbons); [112,113] the CYP1B1 locus is also linked to primary congenital glaucoma, and the mechanisms underlying this replicated association are being extensively studied [114,115]. Since AHR-mediated activation of CYP1 genes results in unwanted physiologic consequences (such as the activation of procarcinogens) and is an unwanted drug effect, pharmaceutical companies routinely screen new chemical entities for CYP1A induction potential (a detrimental property).

12.6 FLAVIN-CONTAINING MONOOXYGENASES

The mammalian flavin-containing monooxygenases (FMO) are a family of microsomal flavoproteins that catalyze the oxidation of a wide range of nucleophilic heteroatom-containing compounds. There are five functional FMO genes and several pseudogenes in humans. The FMO genes are expressed in a tissue- and temporal-selective manner. FMO1 is the major fetal isoform, and FMO3 is the major adult isoform [116]. FMO3 is the most abundantly expressed FMO in adult human liver, with levels comparable to some of the abundant CYPs and, as such, is the most relevant for drug metabolism ([117,118] and references therein). Similar to the other FMO, FMO3 has a broad substrate specificity and is involved in the metabolism of commonly used drugs including cimetidine, ranitidine, clozapine, methimazole, itopride, ketoconazole, tamoxifen, and sulindac sulfide [119–123]. Numerous polymorphisms have been reported in the *FMO3* gene (http://human-fmo3.biochem.ucl.ac.uk/Human_FMO3/Tables/tableall.html). Genetic variants resulting in FMO3 deficiency are responsible for the phenotype of trimethylaminuria, otherwise known as *fish-odor syndrome*. Allelic variants that result in FMO3 deficiency are associated with the inability to metabolize the tertiary amine, trimethylamine (TMA), that is derived *in vivo* from the bacterial degradation of dietary choline, carnitine, and lecithin and found in various dietary sources including marine fish, beetroot, and legumes. Accumulation of TMA in the body results in a malodor resembling decaying fish. Genetic variants of FMO3 are also associated with altered metabolism of various substrates, including sulindac, ranitidine, and benzydamine [124–127].

12.7 ARYLAMINE *N*-ACETYLTRANSFERASES

The arylamine NATs are a family of drug-metabolizing enzymes that catalyze the transfer of an acetyl group from acetyl-CoA to the terminal nitrogen of substrates including isoniazid, some sulfonamides, dapsone, phenelzine, hydralazine, and procainamide ([128,129] and references therein). There are two functional NATs in humans, NAT1 and NAT2, and both genes contain sequence polymorphisms affecting activity. As mentioned in Section 12.2, the identification of the polymorphic inactivation of the antitubercular drug isoniazid is one of the early success stories of pharmacogenetics, and as such, this immense body of work has been extensively reported and reviewed [5–9]. The molecular genetic bases of the acetylation

polymorphism are well characterized, and individuals can be classified as “slow” or “rapid” acetylators based on the genotype. Slow acetylators often experience adverse reactions in response to drugs such as isoniazid, sulfonamides, procainamide, and hydralazine, whereas rapid acetylators may not respond to isoniazid and hydralazine [5,6,130–132]. Information related to acetylator status is included in several drug labels (http://www.fda.gov/cder/genomics/genomic_biomarkers_table.htm).

12.8 UDP-GLUCURONOSYLTRANSFERASES

The UGTs superfamily of phase II drug-metabolizing enzymes catalyzes the transfer of the glucuronic group from uridine diphosphoglucuronic acid to a substrate, thereby increasing polarity and facilitating excretion of the substrate in bile or urine. UGTs are responsible for the conjugation of endogenous compounds such as bilirubin, steroid and thyroid hormones, and bile acids and exogenous compounds including drugs (e.g., irinotecan, clozapine, and buprenorphine), dietary components, environmental contaminants, and chemical carcinogens [133–135]. The 18 functional UGT proteins are encoded by 2 gene families, *UGT1* and *UGT2*, which comprise 3 subfamilies—*UGT1A*, *UGT2A*, and *UGT2B*. The major members of these families are described below.

12.8.1 *UGT1A*

The *UGT1A* subfamily is most interesting in that the entire *UGT1A* subfamily is derived from a single gene locus comprising 17 exons that encode 9 functional proteins (*UGT1A1* and *UGT1A3–1A10*). Each *UGT1A* isoform is encoded by a unique exon 1 and common exons 2, 3, 4, and 5 downstream, which means that all the *UGT1A* proteins have a unique N-terminal substrate-binding region but a common C-terminal cosubstrate-binding domain. Recent studies suggest that there may be additional genetic diversity at the *UGT1A* locus resulting from alternative splicing but requires additional characterization [136,137].

UGT1A1 and *UGT1A6* are expressed in the liver and are the major contributors toward xenobiotic metabolism; the other *UGT1A* members are expressed extrahepatically and therefore may play less roles in overall xenobiotic metabolism.

UGT1A1 is the most extensively studied member of the UGT superfamily because of its level and location of expression and its importance in the metabolism of endogenous and exogenous compounds. It is the primary enzyme responsible for the conjugation of bilirubin and also has an important role in conjugation of xenobiotics such as irinotecan and nilotinib. Genetic alterations that affect *UGT1A1* expression or function are associated with severe familial forms or milder, more common, usually asymptomatic forms of unconjugated hyperbilirubinemia (Crigler–Najjar type I and II disorders and Gilbert’s syndrome, respectively) [138–143]. A common dinucleotide (TA) repeat polymorphism within the TATA-box region of the *UGT1A1* promoter affects *UGT1A1* expression level and glucuronidation capacity. On the basis of the number of dinucleotide TA repeats [A(TA)_{*n*}TAA...], four different alleles are identified—*UGT1A1**1 (*n* = 6), *UGT1A1**33 (*n* = 5), *UGT1A1**28 (*n* = 7), and *UGT1A1**34 (*n* = 8). In general, there is an inverse correlation between the number of TA dinucleotide repeats and level of *UGT1A1* expression [141,144,145]. The most common (or wild type)

allele has six TA repeats, while the most common variant allele (*UGT1A1**28) has seven repeats and is associated with decreased glucuronidation capacity for *UGT1A1* substrates. While the promoter polymorphism is highly prevalent (and most relevant from a drug disposition perspective) in the Caucasian and African population, another polymorphism (*UGT1A1**6) that comprises an amino acid change (Gly71Arg) affecting *UGT1A1* activity is predominant in the Japanese population and is associated with hyperbilirubinemia in this population [133,146,147].

The *UGT1A1**28 polymorphism was extensively characterized during studies of the anticancer drug, irinotecan, and information related to this polymorphism is included in the drug label for its association with adverse events (see also labeling information for nilotinib) (http://www.fda.gov/cder/genomics/genomic_biomarkers_table.htm). Irinotecan is a camptothecin derivative that shows antitumor activity via topoisomerase inhibition [148]. The active metabolite of irinotecan, SN-38, is formed by carboxylesterase enzymes in the liver. *UGT1A1* is the primary enzyme responsible for the subsequent conjugation and elimination of SN-38 in bile and urine [149]. The dose-limiting toxicities of irinotecan (severe diarrhea and neutropenia) are attributed to the increased levels of the active metabolite SN-38 resulting from decreased glucuronidation and elimination. Reduced expression of *UGT1A1*, due to polymorphisms within the gene, is associated with lower SN-38 glucuronidation and irinotecan toxicity [141,150–152].

Approximately 10% of the North American population is homozygous for the *UGT1A1**28 allele. These patients have lower *UGT1A1* activity, reduced capacity for eliminating SN-38, and consequently are at increased risk for neutropenia. A reduced initial dose of irinotecan is recommended for these patients. Results for patients who are heterozygous for the *UGT1A1**28 allele are mixed, but, in general, these individuals are thought to tolerate normal doses of irinotecan. Other polymorphisms affecting *UGT1A1* activity will theoretically have similar implications for irinotecan toxicity, but the associations are not as yet well characterized.

The other important *UGT1A* subfamily member, *UGT1A6*, is involved in the metabolism of acetaminophen, aspirin, and other nonsteroidal anti-inflammatory agents. Missense mutations within the *UGT1A6* gene result in reduced catalytic activity toward at least some *UGT1A6* substrates [153]. The reports of high linkage disequilibrium between *UGT1A6* missense polymorphisms and *UGT1A1**28 alleles suggest an importance of haplotype structure and the need for caution when interpreting association results.

UGT2B7 and *UGT2B15* are important drug-metabolizing enzymes (substrates include morphine, epirubicin, zidovudine, gemfibrozil, and oxazepam) and are also involved in the metabolism of endogenous substances including steroid hormones. Common missense polymorphisms in these genes may affect glucuronidation activity in a substrate-specific manner, but the clinical relevance of drug metabolism is yet unclear (see Refs 133,135, and 154 and references therein).

12.9 SULFOTRANSFERASES

There are two classes of sulfotransferases in vertebrates—the membrane-bound sulfotransferases found in the Golgi apparatus and the soluble, cytosolic forms [155]. The membrane-bound sulfotransferases act on endogenous macromolecules and are not

discussed further since they are not known to metabolize xenobiotics. The cytosolic sulfotransferases metabolize hormones and xenobiotics. The soluble sulfotransferases catalyze the transfer of the sulfonyl group from 3'-phosphoadenosine 5'-phosphosulfate to the hydroxyl, sulfhydryl, amino, or N-oxide group of a variety of substrates.

The human cytosolic SULT enzymes are a superfamily comprising 12 isoforms. Of all SULT family members, SULT1A1 is the most relevant for drug metabolism because of its abundance in the liver and its broad substrate specificity. SULT1A1 is involved in the metabolism of various hormones and xenobiotics (e.g., acetaminophen, minoxidil, and the active metabolites of tamoxifen) (see Ref. 156 and references therein). Considerable interindividual variability, largely attributed to inherited factors, is observed in platelet SULT1A1 activity and thermal stability [157,158]. The most common variant allele, *SULT1A1**2 (with a nonsynonymous SNP, Arg213His), is associated with decreased SULT1A1 activity and thermal stability [159,160]. Additionally, two polymorphisms within the 5'-flanking region of the *SULT1A1* gene are also associated with variability in SULT1A1 activity, but these polymorphisms are in linkage disequilibrium with the *SULT1A1**2 polymorphism, and therefore, the effect of these and the *SULT1A1**2 polymorphism on activity may be attributed to the haplotype [161]. However, the SULT1A1*2 polymorphism (and 5'-flanking region polymorphisms) only account for a portion of the inherited variability in SULT1A1 activity. The more recent identification of relatively common copy number variability of the *SULT1A1* gene explains a greater portion of the variability in activity. Similar to the copy number variability observed for CYP2D6, a *SULT1A1* gene deletion/duplication event results in individuals being "slow sulfators" or "rapid sulfators" [162]. Therefore, any genotype–phenotype correlations for *SULT1A1* must include an assessment of both copy number and SNPs. The contribution of both CNVs and SNPs to variability in SULT1A1 activity is comprehensively described by Hebring *et al.* [163].

12.10 DRUG TRANSPORT PROTEINS

Drug transport proteins are important determinants of drug pharmacokinetics and pharmacodynamics. Drug transporters affect all aspects of ADME—drug absorption, distribution, and elimination are affected by transport across tissues, and metabolism is affected by controlling access of the drug to the site of metabolism. Transporters also affect drug pharmacodynamics by their role in allowing access to the site of action [e.g., P-glycoprotein (P-gp) expression at the blood–brain barrier]. Variability in the expression or function of drug transport proteins can affect the PK or pharmacodynamic profiles of a drug and hence efficacy, adverse event, or drug–drug interaction profiles. Drug uptake and efflux from tissue are carried out by over 400 transporters in 2 major superfamilies—the solute carrier (SLC) transporters and the ATP-binding cassette (ABC) transporters, respectively [164,165]. The SLC transporter family comprises uptake transporters, which mediate the passage of small molecules across biological membranes along concentration gradients in a process known as *facilitated diffusion*. The ABC transporters utilize energy from ATP hydrolysis to transport substrates across biological membranes, either against or along concentration gradients, in a process known as *active transport*. The combined, concerted action of uptake and efflux transporters within the different membranes is a critical determinant of the extent and net direction of drug movement in or out of organs.

As with the drug-metabolizing enzymes, most drug transport proteins contain polymorphisms, but genotype–phenotype relationships are not as well characterized as those of drug-metabolizing enzymes. Comprehensive discussion of the pharmacogenetics of drug transporters is outside the scope of this chapter, but the topic is well reviewed in the literature [166–168]. The International Transporter Consortium, comprising industry, regulatory, and academic scientists, identified transporters that are currently known to be important determinants of drug pharmacokinetics [169]. This list of transporters is provided in Tables 12.3 and 12.4 and annotated for PG relevance. Only the most clinically relevant transporters are described below.

12.10.1 OATP

The organic anion transporting polypeptides (OATPs) (gene family—*SLCO*), belong to the SLC family of transporters, have broad substrate specificity and are expressed in multiple tissues including liver, gut, and blood–brain barrier. OATP1B1, which is predominantly expressed in the liver and has a major role in the transport of several drugs, including rifampin, the statins (atorvastatin, rosuvastatin, pravastatin, and more), and repaglinide, is probably the best-characterized member of the OATP family. OATP1B1 is encoded by the *SLCO1B1* gene. Allelic variants of *SLCO1B1* are associated with decreased transporter activity (e.g., *SLCO1B1**1b, *2, *3, *4, *5, *6, *9, *13, *15, and *17) [170–172] and are clinically relevant since they affect the disposition or effect of several drugs including pravastatin, fexofenadine, atrasentan, and repaglinide [173–180].

12.10.2 ABC Transporters

The ABC transporters are encoded by 49 different genes classified into 7 subfamilies based on sequence homology (ABCA–ABCG; nutrigene.4t.com/humanabc.htm). The ABC transporters are responsible for the transport of various substrates across membranes against a concentration gradient, using energy provided by ATP. Many members of this family are known to confer multidrug resistance to cancer chemotherapy.

P-gp is encoded by the multidrug resistance 1 gene (*MDR1/ABCB1*), and because of clinical relevance, it is the best-characterized member of the ABC transporter family. The *MDR1* gene was aptly named as such for its ability to transport various anticancer agents such as docetaxel, etoposide, paclitaxel, topotecan, and vinblastine out of the cell, thereby conferring the phenotype of multidrug resistance. However, we now know P-gp has a broad substrate specificity that extends across a wide range of therapeutic agents including antiarrhythmics (e.g., digoxin, verapamil), antibiotics (e.g., erythromycin), and immunosuppressants (cyclosporine, tacrolimus) [168]. P-gp is expressed in multiple tissues including the brain, small and large intestines, kidney, liver, and testes and is an important mediator of drug efflux. Over 105 variants have been detected within the *ABCB1* gene [167,181–185], and many studies have been performed to characterize the functional consequences of these variations. Much of the research on *ABCB1* pharmacogenetics has focused on three SNPs that are in linkage disequilibrium—two synonymous SNPs (1236 C>T in exon 12, 3435 C>T in exon 26) and a nonsynonymous SNP (2677G>T, resulting in an amino acid change at position 893, A893S). PG studies investigating the relationship between these (and other) *ABCB1* polymorphisms and the pharmacokinetics of well-characterized P-gp

TABLE 12.3 Clinically Relevant SLC Transporters and Associated Pharmacogenetic Information

Transporter/Alias (Gene)	Organs/Cells	Pharmacogenetic Relevance	References
OATP1B1/OATP-C, OATP2, LST-1 (<i>SLCO1B1</i>)	Hepatocytes (sinusoidal)	Consistently replicated associations between genotype and clinical pharmacokinetics	12,169,180
OATP1B3/OATP-8 (<i>SLCO1B3</i>)	Hepatocytes (sinusoidal)	<i>In vitro</i> evidence of common functional variants, but not yet associated with clinical pharmacokinetics	12,169,180
OAT1 (<i>SLC22A6</i>)	Kidney proximal tubule, placenta	Functional genetic variants exist but are uncommon	12,169
OAT3 (<i>SLC22A8</i>)	Kidney proximal tubule, choroid plexus, blood–brain barrier	Functional genetic variants exist but are uncommon	12,169
OCT2 (<i>SLC22A2</i>)	Kidney proximal tubule, neurons	Association between genotype and clinical pharmacokinetics of at least one drug	12,169,188
OATP1A2/OATP-A (<i>SLCO1A2</i>)	Brain capillaries endothelia, cholangiocytes, distal nephron	<i>In vitro</i> evidence of common functional variants, but not yet associated with clinical pharmacokinetics	12,169,180
OATP2B1/OATP-B (<i>SLCO2B1</i>)	Hepatocytes (sinusoidal), endothelia	<i>In vitro</i> evidence of common functional variants, but not yet associated with clinical pharmacokinetics	12,169,180
OCT1 (<i>SLC22A1</i>)	Hepatocytes (sinusoidal), intestinal enterocytes	Association between genotype and clinical pharmacokinetics of at least one drug	12,169,189–191
PEPT1 (<i>SLC15A1</i>)	Intestinal enterocytes, kidney proximal tubule	Functional genetic variants exist but are uncommon	12,169,191
PEPT2 (<i>SLC15A2</i>)	Kidney proximal tubule, choroid plexus, lung	<i>In vitro</i> evidence of common functional variants, but not yet associated with clinical pharmacokinetics	12,169
MATE1 (<i>SLC47A1</i>)	Kidney proximal tubule, liver (canalicular membrane), skeletal muscle	Functional genetic variants exist but are uncommon	12,169,192,193
MATE2-K (<i>SLC47A2</i>)	Kidney proximal tubule	<i>In vitro</i> evidence of functional variants, but not yet associated with clinical pharmacokinetics	12,169,193

substrates, such as digoxin, fexofenadine, and cyclosporine A, have yielded inconsistent or even contradictory results ([186] and references therein). Therefore, while the importance of P-gp for drug disposition is indisputable, the clinical consequences of *ABCB1* polymorphisms (specifically, association between genetic variants and drug pharmacokinetics) remain unclear, and the utility of *ABCB1* genetic testing remains to be determined.

The ABCG family comprises several members that are thought to form homo- or heterodimers for transporter function. The most clinically relevant member of this family is ABCG2 [also known as *breast cancer resistance protein* (BCRP)] that was initially identified by and named for its role in conferring multidrug resistance to cancer cell lines. Polymorphisms within the *ABCG2* gene are associated with gefitinib-induced diarrhea and with altered pharmacokinetics of several drugs including irinotecan, rosuvastatin, sulfasalazine, topotecan, diflomotecan, and 9-aminocamptothecin, but contradictory results have been reported for other substrates [187].

12.11 DISCUSSION

Genetic factors are important contributors toward variability in drug pharmacokinetics. Understanding the genetic bases for PK variability can allow for the safer and more efficacious use of drugs. Increased understanding of the genetic bases for PK variability in a drug is being encouraged by regulatory agencies including the US FDA, European Medicines Agency (EMA), and the Pharmaceuticals and Medical Devices Agency, Japan (PMDA), such that the pharmacogenetics of new drugs are better characterized before market launch. Pharmaceutical companies now routinely dedicate effort toward determining whether PG factors contribute to observed PK variability. Such efforts include routine collection of DNA samples in clinical PK studies and appropriate analyses of these samples for functional variants in the enzymes and transporters for which the drug is a substrate. Early generation of this information has been used to inform dose selection in early trials, provide information for population PK modeling, and contribute toward safer clinical trials.

The immense amount of information on the genetics of drug disposition, the tremendous advances in sequencing and genotyping technologies, and the decreasing costs of these technologies may serve further to the stratified use of drugs, such that all factors, including age, weight, medical history, and genetics are used in the treatment decision-making process and further “personalizing” therapy.

13.1 INTRODUCTION

Nearly two million adverse drug reactions are reported annually, of which 26% can be attributed to avoidable drug–drug interactions (DDIs) [1]. Predicting potential DDIs is one of the most important activities that a pharmaceutical company undertakes before the approval of any new drug. DDI predictions are primarily governed by elucidation of the metabolism of any new entity. Seventy-three percent of the top 200 drugs are cleared primarily by metabolism, of which 75% of the metabolism occurs due to cytochrome P450 enzymes, a superfamily of oxidative enzymes found mainly in the liver and also distributed in the intestine, kidneys, adrenal glands, lungs, and other organs. Of all the P450 enzymes, CYP3A4, CYP2C9, CYP2C19, and CYP2D6 are responsible for more than 80% of the oxidative metabolism of the top 200 drugs and hence are of special interest to the drug metabolism scientist [1]. Of late, other P450 enzymes such as CYP1A2, CYP2B6, and CYP2C8 have been recognized to be of increasing importance because of an expansion of drugs metabolized by these enzymes, their role in formation of toxic metabolites, and the occurrence of genetic polymorphisms affecting activity.

Although known about for many years, DDIs were generally mild to moderate in severity and could be managed clinically. However, the clinical importance of DDIs truly became front and center with the occurrence of the life-threatening and sometimes fatal interaction of combinations such as terfenadine–ketoconazole and terfenadine–erythromycin, for example, Refs 2–4. In these cases, the potentially fatal arrhythmic condition, Torsades de Pointes, was induced by the coadministration of

these agents. It was later learned that this interaction was due to a reduced metabolism of the parent drug, terfenadine, which normally undergoes rapid metabolism to a non-cardiotoxic metabolite, fexofenadine. These and similar interactions that have been identified subsequently clearly demonstrated that as medications become more potent, the potential clinical ramifications of a DDI can also become more pronounced.

When more than 25% of the clearance of a given drug is carried out by a single P450 enzyme, there is cause for concern from a DDI perspective [5]. However, a confounding factor in predicting P450-mediated metabolism of a compound is the promiscuous nature of these enzymes, allowing them to catalyze the metabolism of a wide variety of substrates with sometimes overlapping substrate specificity. A practical implication of this is that some drugs may be a substrate to a particular P450 but an inhibitor of another P450. In addition, P450 enzymes tend to be allosteric enzymes and in fact may have two or three catalytic sites within their active site, sometimes necessitating the use of multiple probe substrates for a single enzyme such as CYP3A4. Finally, the interplay of P450 enzymes with other metabolizing enzymes such as uridine diphospho glucuronosyltransferase (UGT) enzymes and glutathione S-transferase (GST) enzymes, and transporters such as P-glycoprotein (P-gp) also serve to confound the prediction of DDIs. Indeed, the US Food and Drug Administration (FDA) has released guidance documents for conducting experiments and clinical studies related to DDIs [6,7]. The focus of this chapter is to elucidate the basic concepts of the various kinds of inhibition of drug-metabolizing enzymes, the equations that can be used to describe the various types of inhibition and the prediction of the *in vivo* inhibition DDIs utilizing *in vitro* data.

13.2 BASIC INHIBITION MECHANISMS

The interaction of two drugs to produce inhibition of single or multiple enzymes can lead to DDIs with clinical consequences. Hence, the determination of a candidate drug's ability to inhibit metabolizing enzymes forms a critical part of drug discovery screens. *In vitro* studies can also help determine a drug's potency to inhibit drug-metabolizing enzymes, typically through determination of the K_i (inhibition constant) or IC_{50} (concentration producing 50% inhibition). Kinetically, enzyme inhibition can be categorized into four main types—competitive, noncompetitive, uncompetitive, and mixed. In addition, irreversible inhibition, also termed *mechanism-based inhibition*, is increasingly being observed (but will be dealt with in another chapter of this series).

The first step in the determination of the ability of a compound to inhibit an enzyme is typically the determination of its IC_{50} toward a particular enzyme–substrate combination. This involves measurement of the turnover of the substrate in the absence and presence of the purported inhibitor. Either fluorescent or luminescent assays have been used in the past for high throughput determinations of IC_{50} values for candidate compounds. Both technologies involve the use of prefluorescent (or preluminescent) substrates that are incubated with recombinant enzymes with and without inhibitor, with the fluorescence or luminescence occurring following metabolism [5] and any decrease in signal as compared to incubations absent, the inhibitor being used as a measure of inhibition. However, lack of isoform specificity (thus, requiring use of expressed enzymes) and sometimes unusually high K_m values for the reaction and frequent occurrence of atypical kinetics with these compounds has greatly limited their

utility. Thus, because of advances in LC-MS/MS technology, use of specific probe substrates and monitoring of metabolite production by mass spectrometric methods has become the standard for inhibition kinetics determinations. Particularly with the speed and resolution of ultra performance liquid chromatography (UPLC) and the selectivity of an LC-MS/MS, minimal method development is required and highly specific substrates can be used to measure turnover. Cassette analysis wherein multiple compounds are dosed together can further enhance throughput, and utilizing robotics for sample processing can automate most of the process. However, again one must be cautious when using cassette methods because of isoform cross-reactivity of compounds.

Commonly, early in the drug discovery process, only IC_{50} values are determined since this requires just one substrate concentration (typically at or near K_m) and incubation of inhibitor at multiple levels with an enzyme source. Compounds exhibiting IC_{50} values less than $1\ \mu M$ are generally considered high risk to cause *in vivo* DDIs, while those exhibiting IC_{50} values greater than $30\ \mu M$ are generally considered to be low risk [8]. Compounds with IC_{50} values between these extremes are of concern and require additional consideration. When conducting *in vitro* inhibition analyses, solubility of inhibitor and substrate are concerns due to the increasing propensity for compounds to be very lipophilic. In this case, nephelometric methods can be used to assess whether precipitation of compound has occurred [9]. For promising drug candidates that also exhibit a low IC_{50} value toward a particular P450, it may be instructive to conduct additional experiments to determine K_i values (which are independent of substrate concentration) and the mechanism of inhibition. When determining K_i values, initial substrate conditions (turnover less than 10%), substrate not at saturation conditions (which would diminish inhibitory effects), and the possibility of atypical kinetics need to be taken into account.

The FDA recommended list of *in vivo* substrates and inhibitors (as positive controls) include the following substrate and inhibitor pairs, respectively, caffeine and fluvoxamine for CYP1A2, efavirenz and ticlopidine for CYP2B6, rosiglitazone and phenelzine for CYP2C8, *S*-warfarin and fluconazole for CYP2C9, omeprazole and fluvoxamine for CYP2C19, dextromethorphan and quinidine for CYP2D6, chlorzoxazone and disulfiram for CYP2E1, and midazolam and ketoconazole for CYP3A4/3A5 [10]. To accurately determine the type of inhibition and the K_i of the inhibitor require incubations of at least 3–4 concentrations of the substrate (bracketing the K_m) and at least 3–4 concentrations of the inhibitor. In contrast to IC_{50} values, K_i values are independent of substrate and protein concentration. Diagnostic plots, such as the Eadie–Hofstee and Dixon plots, can help determine the nature of the inhibition and give an approximate estimation of the various parameters involved [11]. The various types of *in vitro* systems that can be used have been reviewed in another chapter, but briefly, liver microsomes are considered the gold standard for *in vitro* studies and provide an excellent representation of all the enzymes present in the system. However, it should be recognized that they do not include cytosolic enzymes and transporters as well as several conjugation enzymes. If one suspects these other enzymes or transporters are involved in a compound's metabolism, use of human hepatocytes (fresh or cryopreserved) is likely a more appropriate system [12].

13.2.1 Competitive Inhibition

In competitive inhibition, the substrate and inhibitor directly compete for the catalytic site of the enzyme (Scheme 13.1). Commonly, both the inhibitor and substrate are catalyzed by the enzyme; hence, any two substrates for a single enzyme would be in competitive inhibition. Competitive inhibition (Fig. 13.1) is the most commonly observed type of inhibition and the kinetic scheme for this phenomenon is given in Scheme 13.1.

Scheme 13.1

Figure 13.1 Competitive inhibition diagnostics. (a) The EH plot and (b) the Dixon plot. Both the plots can be used to diagnose competitive inhibition and calculate $V_{\max}$, K_m , and K_i .

For the purposes of this chapter, $V_{\max}$ and K_m are the Michaelis–Menten kinetic parameters for the substrate in the absence of inhibitor, while $V_{\max, \text{app}}$ and $K_{m, \text{app}}$ are the parameters in the presence of inhibitor and K_i is the first-order inhibition rate constant (k_{-1}/k_1).

In the case of competitive inhibition, in addition to the usually formed [ES] species, an [EI] species is also reversibly formed. Using a subsaturating concentration of inhibitor and high enough concentration of substrate, maximum ($V_{\max}$) velocities can be obtained. Essentially, at high enough substrate concentrations, the complex shifts away from [EI] and toward [ES], hence $V_{\max}$ is unaltered. However, to achieve this shift requires high enough substrate concentrations to offset the inhibitor concentrations; the result being increased K_m . The diagnostic plots for this kind of inhibition are given in Fig. 13.1 [11]. As seen in the Lineweaver–Burk reciprocal plot (Fig. 13.1a), the various fitted lines intersect at the y-axis at $1/V_{\max}$, while the x-axis intercept is equal to $1/K_{m, \text{app}}$. The various slopes and intercepts can be solved to obtain $V_{\max}$, K_m , and K_i . The Dixon plot (Fig. 13.1b) can also be used to diagnose competitive inhibition and to solve for all the kinetic parameters.

From the scheme above, one can derive the kinetic equation for competitive inhibition (Eq. 13.1), which is used to estimate the relevant variables:

$$v = \frac{V_{\max}[S]}{K_m \left(1 + \frac{[I]}{K_i}\right) + [S]} \quad (13.1)$$

where [S] is the substrate concentration and [I] the inhibitor concentration and the other parameters are as described previously.

It is worthy to note that IC_{50} can be directly related to K_i by application of the Cheng–Prusoff Equation [13] (Eq. 13.2):

$$IC_{50} = K_i \left(1 + \frac{[S]}{K_m}\right) \quad (13.2)$$

In this case, if $[S] = K_m$ in the *in vitro* incubations, then $IC_{50} = 2 \times K_i$. Likewise, if $[S] \ll K_m$ (as in *in vivo* situations) then $IC_{50} \approx K_i$.

13.2.2 Noncompetitive Inhibition

In noncompetitive inhibition, the inhibitor can complex with either the free enzyme [E] or an enzyme–substrate complex [ES] to form an unproductive enzyme–substrate–inhibitor [ESI] complex (Scheme 13.2). In addition, the substrate can bind to the enzyme active site even when the inhibitor is already bound to the enzyme. Noncompetitive inhibition occurs when the inhibitor binds to an allosteric location on the enzyme or occupies a spot in the active site exclusive of the catalytic site. This could result in conformational changes in the enzyme or altered substrate binding. For example, curcumin noncompetitively inhibits CYP2C9 and CYP2D6, while olanzapine noncompetitively inhibits CYP2C9 and CYP3A4 [14,15]. The kinetic scheme for noncompetitive inhibition is given in Scheme 13.2.

Since [I] can complex with both [E] and [ES], forming either [EI] or [ESI], increasing the concentration of [S] is inadequate to drive the equilibrium of the reaction all the way toward the [ES] complex. The presence of the unproductive complex, [ESI],

Scheme 13.2

reduces the effective concentration of [ES] and hence reduces the maximum achievable velocity, $V_{\max}$. Since [S] and [I] bind at different sites on the enzyme, the presence of one ligand (either substrate or inhibitor) does not affect the binding affinity of the other, meaning that [S] can bind to both [E] and [EI] with equal affinity. In addition, the [ESI] complex can dissociate to form [ES] plus [I], of which the [ES] complex is then productive. For these reasons, in noncompetitive inhibition, K_m is unchanged [11]. The diagnostic plots for noncompetitive inhibition are shown in Fig. 13.2 [11]. The reciprocal Lineweaver-Burk plot (Fig. 13.2a) has a y-intercept of $1/V_{\max, \text{app}}$, while the x-intercept is $-1/K_m$. All kinetic parameters can be determined by solving for the intercepts and slope. The K_i can also be obtained from the Dixon plot (Fig. 13.2b).

Figure 13.2 Noncompetitive inhibition diagnostics. (a) The EH plot and (b) the Dixon plot. Both the plots can be used to diagnose competitive inhibition and calculate $V_{\max}$, K_m , and K_i .

The equation for noncompetitive inhibition is given below [11]:

$$v = \frac{V_{\max}[S]}{K_m \left(1 + \frac{[I]}{K_i}\right) + [S] \left(1 + \frac{[I]}{K_i}\right)} \quad (13.3)$$

In this case, IC_{50} is related to K_i by the following equation:

$$IC_{50} = K_i \quad (13.4)$$

13.2.3 Uncompetitive Inhibition

In uncompetitive inhibition, the inhibitor binds only to the [ES] complex resulting in the formation of a catalytically inactive [ESI] complex (Scheme 13.3). Since substrate-bound enzyme is required to make the enzyme amenable to inhibitor binding, the inhibitor cannot directly bind to the enzyme itself without substrate being present [11]. Uncompetitive inhibition is rarely observed exclusively and when observed, usually occurs in association with other types of inhibition. However, examples of this kind of inhibition have been observed with the drug-metabolizing enzymes. For example, meloxicam uncompetitively inhibits quinidine metabolism by CYP3A4 [16]. The kinetic scheme for uncompetitive inhibition is given in Scheme 13.3.

Since [I] binds to [ES] forming an unproductive [ESI] complex, the addition of excess substrate is insufficient to convert all the [ESI] complexes to [ES] complexes, resulting in a reduction in $V_{\max}$. However, since [I] reacts with [ES] forming [ESI], thereby depleting the [ES] pool, the forward reaction of $[E] + [S]$ is favored and thus, likewise, K_m values are also decreased [11]. The diagnostic plots for uncompetitive inhibition are presented in Fig. 13.3 [11]. The Lineweaver–Burk reciprocal plot is (Fig. 13.3a) characterized by parallel lines with y -intercepts of $1/V_{\max, app}$ and x -intercepts of $-1/K_{m, app}$. The Dixon plot (Fig. 13.3b) can be used to directly obtain K_i .

The equation for uncompetitive inhibition (Eq. 13.5) is given below:

$$v = \frac{V_{\max}[S]}{K_m + [S] \left(1 + \frac{[I]}{K_i}\right)} \quad (13.5)$$

Scheme 13.3

Figure 13.3 Uncompetitive inhibition diagnostics. (a) The EH plot and (b) the Dixon plot. Both the plots can be used to diagnose competitive inhibition and calculate $V_{\max}$, K_m , and K_i .

For uncompetitive inhibition, IC_{50} is related to K_i by the following equation:

$$IC_{50} = K_i \left(1 + \frac{K_m}{[S]}\right) \quad (13.6)$$

In this case, if $[S] = K_m$ then $IC_{50} = 2 * K_i$ and if $[S] \ll K_m$ (as is typical of *in vivo* situations) then $IC_{50} \gg K_i$, meaning that *in vivo*, even if the inhibitor exhibits a low K_i , achieving 50% inhibition is unlikely because of low $[S]$ concentrations [13].

With competitive inhibition, IC_{50} values are dependent on the substrate concentration employed and are usually higher than K_i values (and thus, the higher the substrate concentration, the higher the IC_{50} since the inhibitor has to compete with substrate for the active site). In the case of uncompetitive inhibition, the scenario is reversed. Since the inhibitor can only bind the enzyme after the substrate has bound to the enzyme, increasing the substrate concentrations leads to lowering of the IC_{50} . For noncompetitive inhibition, the inhibitor binds to the enzyme at a site different from the substrate-binding site, and this binding is independent of whether the substrate is

bound to the enzyme. Hence, for noncompetitive inhibition, IC_{50} is independent of substrate concentrations [13].

13.2.4 Mixed Inhibition

Mixed inhibition is for the most part a special case of noncompetitive inhibition, wherein the dissociation constants for the formation of [ES], [EI], [ESI] (formed from [ES] + [I] and [EI] + [S]), and [IE] (in cases wherein the formation of [IE] precludes further [S] binding) are different. The discussions of these various kinds of inhibition are beyond the scope of this chapter.

13.3 IN VITRO–IN VIVO CORRELATIONS FOR DRUG–DRUG INTERACTIONS: EXPERIMENTAL AND THEORETICAL FACTORS

13.3.1 In Vitro–In Vivo Correlations for Drug–Drug Interactions

Being able to predict DDIs on the basis of *in vitro* IC_{50} and K_i data is extremely important to pharmaceutical companies developing drugs. The ability to accurately accomplish this would allow for identification of DDI-based liabilities at an early stage. To this end, many groups have proposed *in vitro*–*in vivo* correlations based on drug metabolism kinetic theory and tested the equations for success in predicting clinical DDIs [17–26]. Success is usually measured by comparing predicted DDIs with values obtained from clinical trials. While the basic principles of predicting DDIs using *in vitro*–*in vivo* extrapolations (IVIVES) has remained unchanged, the methodology has constantly been refreshed. Incorporation of various sources of data (microsomes, hepatocytes, *in vivo* data), allowances for the critical inhibitor concentration, inclusion of protein binding, evaluating the role of the intestine in mediating DDIs and other factors have greatly expanded the utility of this work. This section discusses highlights of the vast literature in this area with a view toward the basic tenets underlying each approach. While these approaches were first developed for P450 enzymes, they can be applied to any drug-metabolizing enzyme, such as UGT enzymes [27].

Most drugs are either competitive or noncompetitive inhibitors of P450 enzymes; hence, the vast majority of literature uses Equations 13.1 and 13.3 to assess the effect of an inhibitor on a drug's disposition when calculating intrinsic clearance of the drug when given with an inhibitor. In the following derivations, it is assumed that the inhibitor does not affect the fraction absorbed from the intestine and the protein binding of the drug (i.e., free fraction stays the same). In addition, the well-stirred model is usually applied to model systemic clearance and is assumed below, as well. Finally, it is also assumed that Michaelis–Menten kinetics is also exhibited by the drug of interest, that is, a V_{max} and K_m can be obtained, and when $[S] \ll K_m$, $[S] + K_m \cong [S]$. When Michaelis–Menten kinetics is not applicable, such as in the case of atypical kinetics that can be observed with most P450 enzymes (although most commonly with CYP3A4 and CYP2C9), one has to make additional allowances. In this case (atypical kinetics), the K_m and V_{max} values of the relevant catalytic site (usually the higher affinity or smaller K_m) as determined by estimation using the appropriate atypical kinetic equation should be applied.

Assuming a drug is cleared by two P450 enzymes, with a fraction metabolized by the primary enzyme (f_{m1}), the intrinsic clearance of the drug from *in vitro* data, Cl_{int} is estimated as in the following Equation 17:

$$Cl_{int} = \frac{V_{max1}}{K_{m1}} + \frac{V_{max2}}{K_{m2}} = f_{m1}Cl_{int} + (1 - f_{m1})Cl_{int} \quad (13.7)$$

where V_{max1} and V_{max2} and K_{m1} and K_{m2} are the Michaelis-Menten parameters for enzymes 1 and 2, respectively. The clearance in the presence of the inhibitor (which inhibits only the primary enzyme), $Cl_{int,i}$, at concentration $[I]$ and using the inhibition rate constant K_i is then given by the following equation:

$$Cl_{int,i} = \frac{V_{max1}}{K_{m1} \left(1 + \frac{[I]}{K_i}\right)} + \frac{V_{max2}}{K_{m2}} = \frac{f_{m1}Cl_{int}}{1 + \frac{[I]}{K_i}} + (1 - f_{m1})Cl_{int} \quad (13.8)$$

The ratio of intrinsic clearances (Eq. 13.9) and the ratio of the areas under the curve (AUC, measure of exposure) (Eq. 13.10) are then given by

$$\frac{Cl_{int,i}}{Cl_{int}} = \frac{f_{m1}}{1 + \frac{[I]}{K_i}} + (1 - f_{m1}) \quad (13.9)$$

and

$$\frac{AUC_i}{AUC} = \frac{1}{\frac{f_{m1}}{1 + \frac{[I]}{K_i}} + (1 - f_{m1})} \quad (13.10)$$

where AUC and AUC_i are the areas under the curve in the absence and presence of inhibitor. Equation 13.10 is frequently referred to as the *Rowland-Martin equation* [28]. When only one enzyme is responsible for the metabolism of a drug, that is, $f_m = 1$, the equation reduces to (for competitive and noncompetitive inhibition) the following equation:

$$\frac{AUC_i}{AUC} = 1 + \frac{[I]}{K_i} \quad (13.11)$$

When two P450 enzymes are inhibited by an inhibitor, with inhibition rate constants of K_{i1} and K_{i2} for inhibitors 1 and 2 respectively, then the equation becomes

$$\frac{AUC_i}{AUC} = \frac{1}{\frac{f_{m1}}{1 + \frac{[I]}{K_{i1}}} + \frac{(1-f_{m1})}{1 + \frac{[I]}{K_{i2}}}} \quad (13.12)$$

For uncompetitive inhibition, Equation 13.11 becomes

$$\frac{AUC_i}{AUC} = 1 + \left(\frac{[S]}{K_m}\right) \left(1 + \frac{[I]}{K_i}\right) \quad (13.13)$$

A close examination of Equation 13.10 reveals that successful prediction of DDIs requires confident estimates of $[I]$, K_i , and f_m . While K_i can be reasonably well

Figure 13.4 Role of f_m and I/K_i in AUC changes on inhibition. As seen, when $f_m < 0.5$, the AUC change will not be greater than twofold, hence will not have clinical significance. Also, when I/K_i is less than 2, the AUC ratio changes are not significant.

estimated from *in vitro* studies, and f_m can be determined with some measure of confidence from *in vitro* systems, considerable uncertainty exists about the value of the appropriate inhibitor concentration that will be relevant at the enzyme active site *in vivo*. Figure 13.4 gives a graphical representation of the role of f_m and the ratio $[I]/K_i$ in the AUC change. As seen, if $f_m < 0.5$ then the increase in AUC at even an infinite concentration of inhibitor will never be greater than twofold. Looking at this relationship from a different perspective, if $[I]/K_i$ is less than 2 then even a twofold increase in AUC is only observed when f_m is greater than 0.75. Hence, if $f_m < 0.5$, or if $[I]/K_i < 2$, then the possibility of a twofold AUC change is minimal.

Using the above methodology, generated *in vitro* data were compared to reports of *in vivo* DDIs culled from 193 studies published in the literature involving CYP2C9, CYP2D6, and CYP3A4/5 [18]. Three inhibitor concentrations were evaluated for their degree of contribution to the accuracy of predications: systemic average inhibitor plasma concentration ($[I]_{\text{avg}}$) after repeated oral administration, maximum inhibitor hepatic input concentration ($[I]_{\text{in}}$), and maximum inhibitor systemic plasma concentration after repeated oral administration ($[I]_{\text{max}}$). The equations used in estimating these three inhibitor concentrations are listed below as derived by Ref. 29:

$$[I]_{\text{avg}} = \frac{\left(\frac{D}{\tau}\right)}{\left(\frac{Cl}{F}\right)} \quad (13.14)$$

$$[I]_{\text{max}} = \frac{[I]_{\text{avg}} k \tau}{1 - \exp(-k \tau)} \quad (13.15)$$

$$[I]_{\text{in}} = [I]_{\text{avg}} + \frac{k_a F_a D}{Q_h} \quad (13.16)$$

where D and τ are the dose and the dosing interval, respectively, of inhibitor used in the *in vivo* interaction study, k is the elimination rate constant, k_a is the absorption rate constant, F_a is the fraction absorbed from gut into the portal vein, Q_h is the hepatic blood flow rate, and Cl/F is the oral clearance of the victim drug. The values of k_a , F_a , Q_h , and RB (blood-to-plasma concentration ratio) were assumed by these authors to be 0.1 min^{-1} , 1, 1610 mL/min, and 1, respectively. Unbound $[I]$ concentrations were also calculated by multiplying $[I]$ by the free fraction of inhibitor (f_u). The fraction metabolized (f_m) term was not included in these analyses, hence, the underlying assumption is that $f_m = 1$.

It is generally assumed that only free drug or inhibitor is available to exert its effect. However, in these simulations, the use of unbound inhibitor concentration did not always result in the best predictions. In this case, the use of unbound $[I]$ resulted in a number of false negatives. It was observed that $[I]_{\max}$ and $[I]_{\text{avg}}$ provided similar degrees of accuracy in the predictions, while use of $[I]_{\text{in}}$ resulted in the most accurate predictions. When $[I]_{\text{avg}}$ was used, accuracy of the predictions was 74%, with 7% false positives and 19% false negatives. When $[I]_{\text{avg},u}$ was used, accuracy of the predictions was 59%, with 5% false positives and 36% false negatives. In these latter two cases, fewer accurate predictions, and a higher degree of false negatives were observed, mainly because the $[I]$ values were lower. When $[I]_{\max}$ was used, accuracy of the predictions was 70%, with 9% false positives and 21% false negatives. When $[I]_{\text{in}}$ was used, accuracy of the predictions was 69%, with 29% false positives (mainly from CYP2D6 interactions) 2% false negatives. Hence, false negatives were almost completely eliminated when $[I]_{\text{in}}$ was used; however, the number of false positives was increased.

In a subsequent analysis, it was observed that the use of hepatic input concentration ($[I]_{\text{in}}$) resulted in the best balance between positive and negative interactions and, most importantly, eliminated false negatives [17]. It was also noted that there was a high incidence of false positive predictions, and many true positives were substantially overpredicted when multiple pathways were present and f_m was not included in the AUC equation. Subsequent inclusion of f_m helped reduce the number of false positives, and increased the success in predicting positive or negative interactions increased from 54% to 84%.

Another model for prediction of inhibition DDIs reported that use of $[I]_{\text{avg}}$ provided the most accurate predictions [20] and resulted in the highest number of predictions within twofold of *in vivo* AUC_i/AUC . This work also reported a corresponding reduction in bias and an increase in precision when $[I]_{\text{avg}}$ was used compared with either $[I]_{\text{in}}$ or $[I]_{\text{in},u}$ for a subset of 45 *in vivo* studies. In this case, predictions of AUC ratios for only 9% of the studies were outside twofold of actual when $[I]_{\text{avg}}$ was included in the predictive model, compared with 24% and 60% outliers for predictions in which either $[I]_{\text{in}}$ or $[I]_{\text{in},u}$ were, respectively, included. Overall, the use of the refined data significantly improved the prediction accuracy by 16% and 35% for predictions based on $[I]_{\text{in}}$ and $[I]_{\text{avg}}$, respectively, but use of $[I]_{\text{in},u}$ or $[I]_{\text{avg},u}$ worsened predictions. The use of $K_{i,u}$ was also found to improve predictions. It seems unusual that unbound K_i improves predictions, whereas total $[I]$ are associated with improved predictions. It is unclear why this paradox is observed.

Obach and coworkers also published a comprehensive evaluation of the correlation of *in vitro* predictions and *in vivo* data [21]. In this examination, estimations of K_i and IC_{50} values for drug-substrate combinations conducted in human liver

microsomes were made for CYP1A2, CYP2C9, CYP2D6, CYP3A4, and CYP2C19 enzymes, which together account for most of the observed P450 metabolism *in vivo*. The IC_{50} values of inhibitors toward all the P450 enzymes were rank ordered to determine the propensity of an inhibitor for causing inhibition *in vivo*. This *in vitro* rank order was then compared against similarly ranked *in vivo* data. In only 3 of 21 cases, the *in vitro* IC_{50} rank ordering did not correlate with the rank ordering of the *in vivo* data. An initial comparison of IC_{50} data versus *in vivo* DDIs found that inhibitors with an *in vitro* IC_{50} of less than $1\ \mu M$ were more likely to cause a twofold increase in AUC [21]. Among inhibitors with an *in vitro* IC_{50} of more than $1\ \mu M$, only 3 of 44 inhibitors resulted in a twofold or higher AUC change *in vivo*. Conversely, only two drugs that exhibited an *in vitro* IC_{50} of less than $1\ \mu M$ did not result in at least twofold AUC change *in vivo*. However, the IC_{50} requirement of $1\ \mu M$ was found not to apply in the case of mechanism-based inhibitors. These same authors also reported that unbound hepatic inlet inhibitor concentration, in general, provided the best estimates of change in AUC.

More recently, a new approach to predict DDIs utilizing *in vivo* data has been recently proposed [26]. Potential uncertainty introduced by atypical kinetics, mechanism-based inhibitors, and inability to accurately assess the contribution of intestinal metabolism from *in vitro* data are frequently reasons that *in vitro*–*in vivo* correlations of DDI predictions are not always successful. In an attempt to overcome these shortcomings, in the work of Ohno *et al.*, an apparent inhibition ratio (IR) and contribution ratio (CR), analogous to K_i and f_m , respectively, were defined. Since the largest amount of *in vivo* data were available for CYP3A4, this study examined the feasibility of this approach for that isoform only.

In this work, the CR was determined by the following equation:

$$CR_{CYP3A4} = \frac{Cl_{int,CYP3A4}}{Cl_{int}} \quad (13.17)$$

where $Cl_{int,CYP3A4}$ is the *in vivo* intrinsic clearance mediated by CYP3A4 and Cl_{int} the total *in vivo* intrinsic hepatic clearance. Compounds with a CR of 1 are fully metabolized by CYP3A4, while those with lower values of CR are metabolized by other isoforms (lower the CR, the greater the contribution by other isoforms).

An IR was also calculated from *in vivo* data using the following equation:

$$IR_{CYP3A4} = \frac{[I_{app}]}{[I_{app}] + K_i} \quad (13.18)$$

where $[I_{app}]$ is the apparent time-average unbound liver concentration. Under these conditions, an IR of 1 represents the lowest possible value of K_i and hence the most potent CYP3A4 inhibitor. Values of IR less than 1 signify less potent CYP3A4 inhibitors (lower the IR, the less potent the inhibitor).

The AUC change (for reversible inhibition) is then given by the above equation:

$$\begin{aligned} \frac{AUC_i}{AUC} &= \frac{Cl_{oral} \cdot F_a}{Cl_{oral,i} \cdot F_a} = \frac{Cl_{int}}{Cl_{int,i}} = \frac{1}{1 - CR_{CYP3A4} \cdot \frac{[I_{app}]}{[I_{app}] + K_i}} \\ &= \frac{1}{1 - CR_{CYP3A4} \cdot IR_{CYP3A4}} \end{aligned} \quad (13.19)$$

This equation essentially resembles Equation 13.10 correlating AUC change with f_m and $[I]/K_i$.

In this study, the IR and CR were calculated from 53 *in vivo* data sets, beginning with the assumption that simvastatin exhibited a CR of 1. From the *in vivo* AUC change for simvastatin interactions, the IR for the various inhibitors was calculated. This sequential approach was subsequently applied to 60 data sets to determine the CR and IR for 14 substrates and 18 inhibitors, respectively.

A portion of the data was then used as the training set to estimate CR and IR, while the remaining data set was used to check the accuracy of the predictions. The AUC ratio change was predicted within 67–150% for 50 of the studies (83%) and within 50–200% (twofold) for 57 of the studies (90%) [26]. However, this approach only works if the IR and CR of the inhibitor and the substrate are within the calculated list, meaning that *in vivo* clinical data are needed for this calculation. Thus, only the interaction potential of combinations of substrates and inhibitors from the list can be predicted. However, since the list includes 14 substrates and 18 inhibitors, a total of 252 DDIs can be predicted. However, to use this approach for new chemical entities, additional work and testing will be needed since no *in vivo* data for these compounds would exist.

An expanded review of the above work was conducted to correlate IR with K_i and CR with f_m [24]. *In vivo* and *in vitro* CR (f_m) were highly correlated and 29 of 38 combinations sets were within 50–200% when making the *in vitro* to *in vivo* CR comparison. Because of this correlation, once an *in vivo* CR is determined for a new chemical entity, then its potential for DDIs with the original set of 18 inhibitors described by Ohno *et al.* [26] can be predicted with some degree of confidence. However, the potential for DDIs with an inhibitor from outside of this list would be outside the scope of this method's predictive capabilities. IR values, however, were not well correlated with *in vitro* K_i values. Similarly, the $[I]$ concentration used (systemic unbound, systemic total, systemic maximum, or portal vein unbound concentration) also did not make a significant difference in the predictive abilities of the model. IR was correlated with dose/K_i . The authors did propose that if one used a substrate with a known CR, then a clinical trial could be conducted, wherein the new chemical entity (NCE) is the inhibitor. From this trial, IR values for the NCE can be determined and compounds with high IR values then would be flagged for additional studies.

13.3.2 Role of Intestinal Metabolism

When a drug is taken orally, it may be subject to presystemic metabolism in the intestine. While CYP3A4 is the most prevalent P450 in the gut, other important enzymes such as CYP2C9 and the UGT enzymes are also present. In addition, transporters such as P-gp are also present in the intestine. P-gp is present in the apical (luminal) side of mature intestinal enterocytes, while CYP3A4 is present in the cytoplasm of the intestinal mucosal enterocytes. Drugs that escape the efflux action of P-gp and the metabolic action of CYP3A4 enter the portal vein, wherein they can undergo metabolism by the liver CYPs and other drug-metabolizing enzymes. For some drugs, this degree of presystemic metabolism or efflux in the gut can comprise a substantial fraction of the overall metabolism, thus preventing their systemic uptake. For example, 57% of orally dosed midazolam is lost due to intestinal metabolism [30], and the liver extraction ratio and intestinal extraction ratio are almost the same (0.44 vs 0.43) [31]. Coadministration

of grapefruit juice with compounds is a convenient experiment that can be performed to determine the contribution of the intestine to clearance of a drug, since grapefruit juice reversibly and irreversibly inhibits CYP3A4 in the intestine [32].

Another indicator of the occurrence of gut metabolism is when the fold change in AUC_{oral} /fold change in AUC_{IV} with and without the inhibitor is greater than 1 [33]. In intravenous (IV) dosing with and without inhibitor, only hepatic clearance is affected by the inhibitor, while during oral dosing with and without inhibitor, both hepatic and first pass (absorption and intestinal metabolism) are affected. Hence, the ratio of oral AUC to IV AUC provides a measure of the effect of the inhibitor on first pass clearance. Ratios of up to 2.8 have been observed, indicating significant gut metabolism. However, in addition to inhibiting P450 enzymes, some inhibitors also inhibit P-gp or other transporters, thereby altering absorption [33]. Hence, the fraction absorbed of the drug also needs to be factored into gut-mediated clearance considerations.

Developing correlations for intestinal *in vitro*–*in vivo* correlations for DDIs have been an area of substantial study. Since CYP3A4 is the main enzyme responsible for metabolism in the gut, most correlation attempts have focused on inhibition of this important isoform. Since the principles of inhibition and intrinsic clearance remain the same (V_{max}/K_m is constant for CYP3A4 irrespective of its location), the basic equation governing the ratio of intestinal clearances is analogous to the equation for hepatic clearance (Eq. 13.20) [21]:

$$\frac{Cl_{int,g,i}}{Cl_{int,g}} = \frac{1}{1 + \frac{[I]_g}{K_i}} \quad (13.20)$$

where $[I]_g$ is the estimated concentration of the inhibitor in the intestinal wall during absorption and is estimated from Equation 13.21. $Cl_{int,g,i}$ and $Cl_{int,g}$ are the intestinal intrinsic clearances in the presence and absence of inhibitor, respectively. K_i is the inhibition rate constant in the gut.

The inhibitor concentration is estimated by application of the following equation [21]:

$$[I]_g = \frac{Dk_a F_a}{Q_g} \quad (13.21)$$

where F_a is the fraction absorbed, k_a the absorption rate, D the dose, and Q_g the enterocytic blood flow rate (0.3 L/min average). F_g , the intestinal bioavailability, is a function of the intestinal clearance [34] (Eq. 13.22):

$$F_g = \frac{A}{A + Cl_{int,g}} \quad (13.22)$$

where A is the absorption constant, assumed to be unaffected by the presence of inhibitors.

The F_g ratio is then determined by the following equation [34]:

$$\frac{F_{g,i}}{F_g} = \frac{A + Cl_{int,g}}{A + Cl_{int,g,i}} = \frac{1}{F_g + (1 - F_g) \left(\frac{Cl_{int,g,i}}{Cl_{int,g}} \right)} \quad (13.23)$$

where $F_{g,i}$ and F_g are the intestinal bioavailability in the presence and absence of inhibitor.

Combining these equations, estimation of the change in AUC due to inhibition, incorporating both intestinal and hepatic effects is given by the following equation [21]:

$$\begin{aligned} \frac{AUC_i}{AUC} &= \frac{\left(\frac{Cl_{int}}{F_g}\right)}{\frac{Cl_{int,i}}{F_{g,i}}} = \frac{F_{g,i}}{F_g} \frac{Cl_{int}}{Cl_{int,i}} \\ &= \frac{F_{g,i}}{F_g} \frac{1}{\left(\frac{f_{mCYP3A4}}{1 + \left(\frac{[I]_{in\ vivo}}{K_i}\right)}\right) + (1 - f_{mCYP3A4})} \end{aligned} \quad (13.24)$$

where AUC_i and AUC are the area under curves in the presence and absence of inhibitor and $Cl_{int,i}$ and Cl_{int} are the intrinsic hepatic clearances in the presence and absence of inhibitor. $[I]_{in\ vivo}$ is the systemic or hepatic inhibitor concentration and $f_{mCYP3A4}$ is the fraction metabolized by CYP3A4, since CYP3A4 is the predominant enzyme causing intestinal metabolism.

The ratio of $F_{g,i}/F_g$ must be determined from *in vivo* studies using both IV and oral dosing, in the presence and absence of inhibitors [33]. Such data sets are rare. However, the ratio can also be determined by substituting Equation 13.22 into Equation 13.24. F_g and F_h have to be determined from *in vivo* studies in anhepatic patients or from a combination of *in vitro* and *in vivo* studies [33,34]. Galetin and coworkers have compiled F_g values for 25 drugs [33]. The requirement of having *in vivo* data makes predicting intestinal DDIs more challenging than predicting hepatic DDIs.

With all of this said, the actual value of including intestinal metabolism in DDI predictions remains unclear. One study found that when the physiologically relevant unbound hepatic inlet concentration was used, ignoring the intestinal component of metabolism increased the error [21]. However, another study involving cases of time-dependent inhibition observed that the percentage of cases where predictions were within twofold accuracy actually declined from 90% to 70% when an intestinal component was considered [33]. Another study found that utilization of the intestinal component did not improve or in some cases, worsened the predictions [20]. Predictions were found to be the most accurate (with and without incorporation of intestinal component) for compounds with high intestinal bioavailability (low first pass metabolism, high F_g).

13.3.3 Role of Fraction Metabolized (f_m)

The fraction of the substrate metabolized by a given enzyme (f_m) is another key parameter included in the successful prediction of DDIs from *in vitro* data (Eq. 13.10). Hence, accurate estimation of f_m is critical to the quality of the prediction. Fortunately, f_m can generally be estimated from *in vitro* reaction phenotyping studies, wherein the substrate is incubated with individual recombinant P450 enzymes and the relative contribution of each P450 to the metabolism of the substrate is determined. A more realistic determination of f_m can be obtained from HLMs with and without specific P450 inhibitors. In addition, studies have also used *in vivo* metabolism

data to determine f_m . For example, the role of CYP2D6 in the metabolism of a substrate can be obtained by comparing poor metabolizers with extensive metabolizers [19]. Comparing the formation clearance of metabolites measured in the urine also provides the contribution of an enzyme in formation of a metabolite, provided that metabolite is formed by a single enzyme. Obviously, if multiple enzymes produce a common metabolite, then formation clearances from urine data will be of limited value. The change in f_m in the presence of the inhibitor can also be determined by this technique.

One of the common assumptions made in determining AUC changes due to enzyme inhibition is that f_m remains essentially constant for a certain drug–enzyme combination. However, f_m may vary depending on substrate concentration if K_m is substantially exceeded. At higher substrate concentrations, enzymes with larger K_m values may make a greater contribution to the drug's metabolism than would be the case at lower substrate concentrations. In addition, interindividual variation in terms of individual polymorphisms and variability in quantity of enzymes may also affect f_m values. Hence, an additional complicating factor in DDI predictions is that f_m can vary through the course of the experiment.

Several studies have examined the utility of including an f_m term in their DDI predictions from *in vitro* data [17,19]. Brown *et al.* observed that the number of predictions within twofold of actual increased from 54% to 84% when f_m was incorporated [19]. The percentage of estimations overpredicting changes in AUC decreased from 46% to 15% and the percentage of underpredictions changed from 0% to 1%. Hence, the improvement was due to the reduction in overpredictions which makes intuitive sense, because when f_m is not incorporated in the equation, the underlying assumption is that $f_m = 1$. This generally overestimates the contribution of an individual enzyme, leading to overprediction of DDI potential, when multiple enzymes may in fact be involved [19].

13.3.4 Role of Genotype

A small number of clinical trials have examined the role of genotype in DDIs. Since *in vitro* studies have demonstrated that various polymorphic variants of drug-metabolizing enzymes can be inhibited to different extents, even while employing the same substrate and inhibitor, clinical trials were performed to determine if this effect persisted *in vivo*. For example, when the CYP2C9 inhibitor fluconazole was administered to steady state (400 mg q.d. for 7 days) and then flurbiprofen (a CYP2C9 substrate) was coadministered, individuals with the CYP2C9*1/*1, CYP2C9*1/*3, and CYP2C9*3/*3 genotypes exhibited different responses to the inhibitor [35]. CYP2C9*1/*1 individuals exhibited almost a threefold decrease in flurbiprofen clearance, CYP2C9*1/*3 individuals exhibited a twofold reduction in flurbiprofen clearance, and CYP2C9*3/*3 individuals did not exhibit any change in flurbiprofen clearance in response to the inhibitor. The authors pointed out that although the formation clearance of 4'-hydroxy-flurbiprofen was reduced in all genotypes, since f_m was 10% for *3/*3, the effect on flurbiprofen clearance was minimal [35]. Hence, f_m also played an important role, and since f_m changes from CYP2C9*1 through CYP2C9*3, an interplay existed between f_m and genotype, the end result of which is to protect the lower activity variants from DDIs. In addition to CYP2C9, similar results have been obtained for CYP2D6 and CYP2C19, although in those cases, the

resulting polymorphic protein is nonfunctional resulting in an inactive protein [36,37]. Hence, for polymorphic enzymes, genotype of the individuals can affect the degree of DDI observed.

13.3.5 Role of Protein Binding

The binding of drug or inhibitor to plasma proteins or nonspecific binding to microsomal or hepatocyte proteins results in a decrease in the effective drug concentration and the potential to falsely overestimate K_i values. In the case of nonspecific binding to microsomal or hepatocyte proteins, one must carry out extensive experiments to estimate the true unbound concentration so that appropriate corrections can be made. With respect to binding to plasma proteins, some researchers have proposed carrying out incubations with microsomes or hepatocytes suspended in serum [22,38]. Incubations with freshly isolated rat hepatocytes were performed with and without serum to determine if serum incubations were an appropriate system to predict *in vivo* clearance [38]. Sixteen compounds that were cleared mainly by the liver were tested. When incubations were performed in the absence of serum, a poor correlation ($r^2 = 0.55$) of *in vitro* clearance with *in vivo* clearance was obtained. If fraction unbound in serum was determined separately and multiplied by the clearance values, then the r^2 increased to 0.86, thus accounting for the binding of the drug to the serum. This method was then extended to verify DDIs of four combinations of inhibitor and substrate by performing incubations with cryopreserved hepatocytes suspended in 100% serum [22]. First pass hepatic clearance and systemic hepatic clearance were separately predicted using this system. Ketoconazole–terfenadine, ketoconazole–indinavir, and desipramine–quinidine interactions were well correlated with *in vivo* predictions. The accuracy of the predictions was within 0.46–1.5 of the actual *in vivo* values. In this case, no corrections for microsomal binding or serum protein binding were required and since hepatocytes were used, the role of transporters and conjugation enzymes were also represented. These results are contingent on the proper choice of inhibitor concentration.

Since both K_i and $[I]$ values are affected by protein binding, the inclusion of protein binding corrections has been evaluated in a few studies [20]. Forty-five *in vivo* studies were compared with *in vitro* results generated in the investigator's laboratory. In general, use of $K_{i,u}$ improved DDI prediction twofold accuracy by at least 15%. The number of predictions within twofold increased from 56% to 91%; however, $[I]_{avg}$ was total concentration, not a free concentration. While this is a highly successful prediction, the paradox of using $K_{i,u}$ but $[I]_{total}$ is noteworthy. Use of $[I]_{avg,u}$ and $K_{i,u}$ resulted only in a 42% twofold accuracy with mainly underpredictions being responsible for the error. Use of $K_{i,u}$ was particularly important for lipophilic inhibitors with less than 0.06% free fraction (e.g., miconazole and itraconazole). Hence, while unbound concentrations are important, it is still unclear why using both $K_{i,u}$ and $[I]_u$ results in significant underpredictions.

13.3.6 Non-P450 Metabolism and Drug–Drug Interactions

While the principles of *in vitro*–*in vivo* correlations are the same for non-P450 enzymes as P450 enzymes, the methodology of obtaining the data may be different. The choice of an enzyme system is crucial to the success of the predictions. A recent

review of three test compounds, gemfibrozil, bupropion, and ezetimibe, revealed how the incorrect choice of test system can lead to wrong conclusions [12]. These authors demonstrated that HLMS underpredicted the ability of gemfibrozil to inhibit CYP2C8 in a mechanism-based manner. Since the acyl glucuronide of gemfibrozil was responsible for the interaction, use of human liver microsomes (without uridine 5'-diphospho-glucuronic acid (UDGPA)) prevented the successful prediction of this interaction, whereas use of hepatocytes would have been appropriate for prediction of this DDI [12]. Another drug, bupropion, a CYP2B6 substrate is also a CYP2D6 mechanism-based inhibitor *in vivo*, although *in vitro* human liver microsomal experiments demonstrated a high K_i (low inhibitory potency) for bupropion against CYP2D6. Once again, non-P450 reductases converted the parent to erythro- and threo-hydrobupropion, both of which are potent mechanism-based inhibitors of CYP2D6. In this instance too, use of hepatocytes would have better predicted the DDI than human liver microsomes [12]. In contrast, ezetimibe is a potent mechanism-based inhibitor of CYP3A4 in human liver microsomes, but when administered to humans, it is extensively directly glucuronidated which prevents the mechanism-based inhibition. Hence, choice of *in vitro* system is crucial in the predictions of non-P450-mediated DDIs.

Some DDIs involving the glucuronosyl transferases (UGT enzymes) and altered drug pharmacokinetics have been reported for compounds such as acetaminophen, codeine, zidovudine, carbamazepine, lorazepam, and propafenone [39]. However, in many cases, these pharmacokinetic changes are of minimal to moderate clinical significance. The reasons underlying the relatively infrequent observation of UGT DDIs have been recently reviewed [40]. The relatively high K_m values of UGT enzymes toward common drugs, which are about 10-fold higher than the typical therapeutic drug concentrations, implies that the velocity is far from being saturated, and hence, a competitive inhibitor that increases the K_m will have minimal impact on the enzyme kinetics. Hence, the continuation of linear kinetics will diminish any impact of the inhibitor on AUC. In addition, due to the high K_m values, the affinity of the UGT to the drug is poor at low substrate concentrations; hence, the hepatic extraction ratios of UGT enzymes are typically lower than observed with the P450 enzymes. A lower hepatic extraction ratio also implies a reduced chance for an adverse DDI reaction. Additionally, the key ratio of $[I]/K_i$ is typically lower for UGT enzymes than P450 enzymes, and multiple UGT enzymes usually catalyze a single substrate. For these reasons, UGT-mediated DDIs are lesser in number than P450-mediated DDIs [40].

Adding to the complexity of predicting UGT DDIs is the lack of specific substrates and inhibitors for these enzymes, although lately selective index reactions appear to have simplified the reaction phenotyping problem. The most commonly employed index substrates/reactions for some of the UGT enzymes are β -estradiol (UGT1A1, 3-glucuronide), 1-naphthol (UGT1A6), propofol (UGT1A9), and naloxone (UGT2B7) [41]. A more comprehensive review of index reactions and substrates for UGTs 1A1, 1A3, 1A4, 1A6, 1A9, 2B7, and 2B15 substrates has been presented, but specific inhibitors were not identified [27].

13.3.7 Role of Drug Pharmacokinetics in Predicting DDIs

As previously alluded to, highly extracted drugs are more susceptible to DDIs, since metabolism can be assumed to be a predominant clearance pathway. This assumption

is not true if biliary excretion of the parent is also a significant clearance pathway. Hence, inhibition of metabolism can cause significant decreases in intrinsic clearance, hepatic clearance, and therefore systemic clearance for highly extracted drugs. However, if a drug has a low extraction ratio to start with then metabolism contributes a minimal amount to its clearance, and therefore further inhibition does not change the pharmacokinetic parameters significantly. For highly extracted drugs, inhibition will predominantly cause $C_{\max}$ increases and increased systemic availability, whereas for poorly extracted drugs, inhibition will cause an increase in elimination half-life with no effect on $C_{\max}$ [8].

13.3.8 Role of Circulating Metabolites

While most analyses of DDIs restrict themselves to the concentration of the inhibitor, there are situations in which the metabolites of the inhibitors can also possess inhibitory properties. The oft-cited example is that of norfluoxetine, a metabolite of fluoxetine, which is a more potent inhibitor than the parent [8]. In the case of racemic drugs such as fluoxetine and warfarin, the differential inhibitory capacities of S and R enantiomers of parent and metabolites may also impact DDIs. If the circulating concentration of the metabolite is high enough, and the metabolite exhibits a low enough K_i , significant DDIs can result from contributions of the metabolite. The new FDA MIST (Metabolites in Safety Testing) guidance requires the analysis of metabolites greater than 10% of overall exposure (sum of all peak areas) for safety and efficacy. A recent analysis found greater than 94% of drugs have circulating metabolites or are extensively metabolized, hence with potential for DDIs [42]. The role of circulating metabolites may play a factor in the underprediction of DDIs.

13.3.9 Role of Multiple Binding Sites (Allosterism)

Certain P450 enzymes, notably, CYP3A4 and CYP2C9 have multiple catalytic sites within their active sites. In addition, some UGT enzymes also exhibit this property. A number of reviews have provided detailed descriptions of the mechanisms and kinetics governing atypical kinetics [43–46]. Hence, this section only briefly describes the role of atypical kinetics in DDIs.

A direct implication of enzyme allosterism in DDI predictions is the characteristic of substrate-dependent inhibition, wherein the same inhibitor can exhibit differing K_i values depending on the substrate. Thus, reliance on probe substrate results with the compound of interest as the potential perpetrator inhibitor may be tenuous. Substrate-dependent inhibition has been observed for CYP2C9, CYP3A4, and CYP2D6, where K_i values have been found to differ by orders of magnitude depending on the substrate [35,47–49]. One method of addressing this has been to employ multiple substrates for determination of K_i values, as has been done for CYP3A4, since this enzyme is thought to have up to three catalytic sites within its active site [21,50]. Similar considerations may be true for CYP2C9 as well [51]. Substrate-dependent inhibition has also been observed *in vivo* in a randomized, double-blind crossover three phase clinical trial [52]. Nine subjects were orally administered 50-mg mibefradil or 5-mg isradipine or placebo for 3 days followed by the administration of a single dose of 0.25-mg triazolam. Mibefradil, but not isradipine, was found to increase the AUC, plasma concentration, and elimination half-life of triazolam compared to placebo. Hence, although mibefradil,

isradipine, and triazolam are all substrates of CYP3A4, only mibefradil had an effect on triazolam disposition, demonstrating the *in vivo* relevance of substrate-dependent inhibition.

Other types of atypical kinetics may also confound *in vitro*–*in vivo* correlations and prediction of DDIs, particularly as it relates to the choice of substrate concentrations. For example, in the case of sigmoidal kinetics, use of very low substrate concentrations will lead to the inhibition of the high affinity binding site, while slightly higher concentrations will lead to the inhibition of the lower affinity binding site [51]. In the case of biphasic kinetics, the K_m of interest is usually the higher affinity, lower capacity site; hence, substrate concentrations around the K_{m1} are most appropriate for *in vitro* testing.

In some cases, where competitive inhibition between two substrates is expected heteroactivation can instead be observed. In heteroactivation, the purported inhibitor is actually an activator and increases the turnover of the substrate, while simultaneously undergoing metabolism, for example, dapsone activating flurbiprofen metabolism by CYP2C9 [53]. Thus, determination of whether an interaction actually will occur is confounded by this activation, rather than the expected inhibition.

13.4 CONCLUSIONS

Predicting DDIs is important to the discovery and development of a drug. Unexpected toxicities due to DDIs can lead to adverse patient outcomes, sometimes fatal, causing the withdrawal of a drug from the market. Considering the cost of discovering and bringing to market a new drug, even isolated incidents of DDIs can have potentially serious consequences for both the patient and the manufacturer. Hence, being able to predict (and subsequently cease) development of compounds that have the potential to cause DDIs is crucial to the success of a drug. While the science of predicting DDIs from *in vitro* data has advanced substantially, and the basic principles elaborately elucidated, a 100% prediction success rate has not yet been achieved. Thus, additional research is needed to further refine our capabilities to predict DDIs from *in vitro* data and enhance the drug discovery and development process.

14.1 INTRODUCTION

There are two major concerns with cytochrome P450 (CYP) induction-mediated drug interaction in clinical practice. First, induction may cause a reduction in therapeutic efficacy of comedications. For drugs whose effect is produced primarily by the parent drug, induction would increase the drug's elimination, resulting in lower drug concentrations and decrease the drug's pharmacological effect. Second, induction may create an undesirable imbalance between detoxification and activation as a result of increased formation of reactive metabolites, leading to an increase in the risk of metabolite-induced toxicity. Unlike CYP inhibition, which is an almost immediate response, CYP induction is a slow regulatory process involving gene transcription, replication of RNA, and biosynthesis of protein. Enzyme induction occurs when a drug stimulates the synthesis of more enzyme protein. During CYP induction, it takes time to reach a new steady state level of CYP enzymes as a result of the balance between the rate of biosynthesis and degradation. On the other hand, the induced CYP enzymes return gradually to basal levels via protein degradation after the inducer is discontinued. The purpose of this chapter is to review the effects of CYP induction on pharmacokinetics of drugs and its clinical implications.

14.2 EFFECTS OF CYP INDUCTION ON PHARMACOKINETICS

14.2.1 Theoretical Considerations

Although CYP induction can be readily evidenced by direct measurement of the enzyme amount and activity in the liver in animal studies, it is difficult to perform direct assessment of CYP induction *in vivo* in humans by measuring enzyme amount and activity in the liver, because of ethical consideration and practical limitations. A common but indirect way of assessing the effect of CYP induction in clinical settings is the comparison of plasma AUC of a drug before and after coadministration of an inducer. For this reason, it is important to understand the kinetic relationship between enzyme induction and plasma AUC.

If a drug is metabolized exclusively by the liver, the total clearance (CL_{total}) of the drug can be considered to be equal to the hepatic clearance (CL_H), which can be expressed as Equation 14.1 or Equation 14.2, according to the well-stirred model or parallel-tube model [1]:

$$CL_{\text{total}} = CL_H = Q_H \cdot E = (Q_H \cdot f_u \cdot CL_{\text{int}}) / (Q_H + f_u \cdot CL_{\text{int}}) \quad (14.1)$$

$$CL_{\text{total}} = CL_H = Q_H \cdot E = Q_H \cdot (1 - e^{-f_u \cdot CL_{\text{int}} / Q_H}) \quad (14.2)$$

where Q_H is the hepatic blood flow, E is the hepatic extraction ratio, CL_{int} is the intrinsic clearance, and f_u is the unbound fraction of drug in the blood. Drugs can be further classified as low or high clearance compounds, depending on whether their elimination clearance is enzyme limited or flow limited [1]. Elimination clearance of a drug, which is much less than hepatic blood flow, is termed *enzyme limited*. In contrast, elimination clearance of a drug is termed flow limited when it is equal to or approaching hepatic blood flow.

Following an oral absorption, hepatic bioavailability (F_H) can be expressed as Equation 14.3 or Equation 14.4, depending on the well-stirred model or parallel-tube model.

$$F_H = 1 - E = \frac{Q_H}{(Q_H + f_u \cdot CL_{\text{int}})} \quad (14.3)$$

$$F_H = 1 - E = e^{-f_u \cdot CL_{\text{int}} / Q_H} \quad (14.4)$$

As shown in Equations 14.3 and 14.4, an increase in the CL_{int} as a result of enzyme induction will cause an increase in first-pass metabolism resulting in a decrease in bioavailability. Following an oral administration, the oral AUC_{po} can be expressed as Equation 14.5 or Equation 14.6, according to the well-stirred model or parallel-tube model.

$$AUC_{\text{po}} = \frac{F_H \cdot f_a \cdot \text{Dose}}{CL_H} = \frac{f_a \cdot \text{Dose}}{f_u \cdot CL_{\text{int}}} \quad (14.5)$$

$$AUC_{\text{po}} = \frac{F_H \cdot f_a \cdot \text{Dose}}{CL_H} = f_a \text{Dose} \frac{(e^{-f_u \cdot CL_{\text{int}} / Q_H})}{Q_H(1 - e^{-f_u \cdot CL_{\text{int}} / Q_H})} \quad (14.6)$$

where f_a is the fraction of dose absorbed from the gastrointestinal lumen.

On the other hand, the AUC_{iv} following intravenous administration can be expressed as Equation 14.7 or Equation 14.8.

$$AUC_{iv} = \frac{\text{Dose}}{CL_H} = \frac{\text{Dose}}{\left[\frac{Q_H \cdot f_u \cdot CL_{int}}{Q_H + f_u \cdot CL_{int}} \right]} \quad (14.7)$$

$$AUC_{iv} = \frac{\text{Dose}}{CL_H} = \frac{\text{Dose}}{Q_H(1 - e^{-f_u \cdot CL_{int}/Q_H})} \quad (14.8)$$

To illustrate the effect of enzyme induction on the AUCs of drugs after oral and intravenous administration, computer simulations have been carried out for drugs using Equations 14.5–14.8. For simplicity, the fraction (f_a) of absorption of drug from intestinal lumen and the unbound fraction of drug in plasma are assumed to remain unchanged during enzyme induction. The hepatic blood flow is assumed to be 1500 mL/min for the simulations. As shown in Figs. 14.1 and 14.2, an increase in CL_{int} of a drug caused by enzyme induction always results in a decrease in AUC of the drug, with the exception of high extraction ratio drugs ($E > 0.9$) after intravenous administration.

Figure 14.1 Simulations of effect of enzyme induction on the AUC of drugs after oral administration conducted using Equations 14.5 and 14.6. On the basis of their extraction ratio (E), drugs are divided into high clearance ($E > 0.9$), moderate clearance ($E = 0.5$), and low clearance ($E < 0.1$) drugs. For simplicity, the f_a and f_u are assumed to be unchanged during enzyme induction. The hepatic blood flow is assumed to be 1500 mL/min for the simulations.

Figure 14.2 Simulations of effect of enzyme induction on the AUC of drugs after intravenous administration conducted using Equations 14.7 and 14.8. On the basis of their extraction ratio (E), drugs are divided into high clearance ($E > 0.9$), moderate clearance ($E = 0.5$), and low clearance ($E < 0.1$) drugs. For simplicity, the f_a and f_u are assumed to be unchanged during enzyme induction. The hepatic blood flow is assumed to be 1500 mL/min for the simulations.

As shown in Fig. 14.1, for low clearance drugs ($E < 0.1$), there is no significant difference in the simulations by either using hepatic well-stirred model or using parallel-tube model. For example, for low clearance drugs ($E < 0.1$), a twofold increase in the CL_{int} resulted in a twofold decrease in AUC, independent of hepatic model (well-stirred or parallel-tube model). However, for moderate and high clearance drugs ($E > 0.5$), enzyme induction appeared to have more profound effect on the AUC of drug after oral administration when the simulations were conducted using parallel-tube model compared to that using well-stirred model. For example, for high clearance drugs ($E = 0.9$), a 2-fold increase in the CL_{int} resulted in a 10-fold decrease in AUC when hepatic parallel-tube model was used for simulation, whereas a 2-fold increase in the CL_{int} resulted in a 2-fold decrease in AUC when hepatic well-stirred model was used. As discussed later, clinical data of CYP induction-mediated drug interactions appear to support the notion that hepatic parallel-tube model is more appropriate for prediction of CYP induction-mediated drug interaction, particularly for moderate and high clearance compound, following oral administration. This is consistent with the general belief that parallel-tube model is better than well-stirred hepatic model for describing the disposition of moderate and high clearance drugs [1,2].

Following intravenous administration, an increase in the CL_{int} has little effect on the AUC_{iv} of high clearance drugs ($E > 0.9$) (Fig. 14.2). As shown in Equations 14.1

and 14.2, when the CL_{int} of a drug is much greater than hepatic blood flow (Q_H), the hepatic extraction and clearance are insensitive to changes in CL_{int} of the drug. This is because hepatic blood flow is the rate-limiting step for drug delivery to the liver. Since the elimination clearance of high clearance drugs is hepatic blood flow limited, it is not surprising to see that enzyme induction has little effect on the AUC of high clearance drugs after intravenous administration. On the other hand, the clearance of low clearance ($E = 0.1$) drugs is highly dependent on the enzyme activity. Thus, the clearance of low clearance drug is enzyme limited and sensitive to enzyme induction. As shown in Fig. 14.2, a twofold increase in the CL_{int} resulted in a twofold decrease in AUC of low clearance drugs after intravenous administration. The effect of enzyme induction on the AUC of low clearance drugs after oral dosing is quite similar to that following intravenous administration (Fig. 14.1).

From the above simulations, it becomes evident that the magnitude of AUC reduction caused by enzyme induction is not only dependent on the drug's characteristics, being a low or high clearance compound, but also dependent on the route of administration of the drug.

14.2.2 Route-Dependent CYP Induction

The notion that the magnitude of AUC changes caused by CYP induction is highly dependent on the route of drug administration is best exemplified by the case of pentobarbital–alprenolol interaction. Alprenolol, a high hepatic clearance drug with a clearance of 1200 mL/min which is approaching to the hepatic blood flow of 1500 mL/min in humans, is known to be induced by pentobarbital in humans. In a clinical study, alprenolol was administered orally or intravenously to 5 healthy subjects on 2 different occasions before and after 10–14 daily doses of 100 mg pentobarbital [3]. The AUC_{po} of alprenolol after a 200 mg oral dose decreased significantly from an average of 706–154 ng h/mL with barbiturate treatment. In contrast, the AUC_{iv} of alprenolol following an intravenous administration of 5 mg dose only slightly decreased from 67 to 58 ng h/mL with pentobarbital treatment. There was a 458% decrease in the AUC_{po} of alprenolol after oral dosing but only a 15% decrease in the AUC_{iv} of alprenolol after intravenous administration.

The differential effect of route administration has also been reported for another high clearance drug, verapamil, which has a clearance of > 1000 mL/min in humans. Treatment with rifampicin had little on the AUC_{iv} of (*S*)- and (*R*)-verapamil after intravenous administration of verapamil, whereas it caused a substantial decrease in the AUC_{po} of (*S*) and (*R*)-verapamil after oral administration of verapamil in humans [4]. After rifampicin treatment for 16 days (600 mg/day), the AUC_{po} of active (*S*)-verapamil decreased from an average of 151 to 5 ng h/mL after oral administration (120 mg), while the AUC_{iv} of (*S*)-verapamil decreased from 77 to 61 ng h/mL following intravenous dosing (10 mg). There is a 3000% decrease in the AUC_{po} of active (*S*)-verapamil after oral administration, while only a 20% decrease in the AUC_{iv} of (*S*)-verapamil following intravenous administration. Similar observations of rifampicin's effects were observed for (*R*)-verapamil after oral and intravenous administration.

Rifampicin also had small effect on the AUC_{iv} of nifedipine, a drug with a clearance of 700 mL/min in humans, after intravenous administration, whereas it greatly reduced the AUC_{po} of nifedipine following oral administration [5]. After seven days of rifampicin treatment (600 mg/day), the AUC_{po} of nifedipine decreased from 280 to

18 ng h/mL when a 20 mg oral dose of nifedipine was given. In contrast, the AUC_{iv} of nifedipine only slightly reduced from 38 to 27 ng h/mL, when the drug was dosed intravenously at 20 μ g/kg body weight. There was a 1555% decrease in the AUC_{po} of nifedipin after oral administration, while only a 30% decrease in the AUC_{iv} after intravenous dosing.

From the above examples, it is evident that CYP induction has a little effect on the AUC_{iv} of high clearance drugs after intravenous administration, while it causes a marked decrease in the AUC_{po} of high clearance drugs following oral administration. Kinetically, the AUC_{iv} of a drug after intravenous administration is determined solely by the systemic clearance, as indicated in Equations 14.7 and 14.8. Because the systemic clearance of high clearance drugs is limited by hepatic blood flow, it is insensitive to the changes in enzyme activity. Therefore, for high clearance drugs, an increase of CL_{int} caused by CYP induction will have little effect on the AUC_{iv} after intravenous administration. In contrast, the AUC after oral administration (AUC_{po}) is determined by both systemic clearance and bioavailability, as shown in Equations 14.5 and 14.6. Although the systemic clearance is not sensitive to the changes in enzyme activity for high hepatic clearance drugs, their hepatic first-pass metabolism and bioavailability are very sensitive to the changes in enzyme activity.

Unlike high clearance drugs, enzyme induction yields significant effects on the systemic clearance and thereby AUC for low clearance drugs, independent of the route of administration. The systemic clearance of low clearance drugs is enzyme limited and sensitive to the changes in enzyme activity. Because low hepatic clearance drugs are generally not subject to significant first-pass metabolism, both the AUC_{iv} and AUC_{po} are determined mainly by the systemic clearance. Therefore, an increase in the intrinsic clearance caused by CYP induction will have similar magnitude of inductive effect on both the AUC_{iv} and AUC_{po} of the low hepatic clearance drugs. As shown in Figs. 14.1 and 14.2, it is expected that the magnitude of the changes in the AUC of the low clearance drugs will be quantitatively similar between oral and intravenous administration.

The methadone–rifampicin interaction is a good example that both the AUC_{iv} and AUC_{po} of the low clearance drugs are sensitive to the changes of enzyme activity caused by CYP induction. In a study, the effect of rifampicin (600 mg/day for 5 days) on the pharmacokinetics of methadone has been studied with 12 healthy volunteers [6]. Methadone, a low clearance drug (140 mL/min), is used to treat opiate addiction by preventing opiate withdrawal syndrome. After an intravenous dose (4.5 mg), the AUC_{iv} of methadone decreased from an average of 816 ng h/mL before rifampicin treatment to 259 ng h/mL after rifampicin treatment. Similarly, the AUC_{po} of methadone decreased from an average of 1128 ng h/mL before rifampicin treatment to 282 ng h/mL after oral administration of methadone (10 mg). The rifampicin treatment caused a similar magnitude of reduction of methadone AUC after both oral and intravenous administration. There was a 3.2-fold decrease in the AUC_{iv} of methadone after intravenous administration and a 4-fold decrease in the AUC_{po} of methadone after oral administration.

14.2.3 Clearance-Dependent CYP Induction

Another intriguing aspect of the effect of CYP induction on the pharmacokinetics of drugs is that the magnitude of AUC reduction caused by enzyme induction is dependent on the drug's characteristics, being a low or high clearance compound.

As shown in Fig. 14.1, the magnitude of AUC_{po} reduction after oral administration appears to be greater for high clearance drugs compared to that for low clearance drugs. Cyclosporine, tacrolimus, methadone, alprazolam, diazepam, zolpidem, and zolpiclone are metabolized mainly by CYP3A4 and are categorized as low clearance drugs because their clearance (<200 mL/min) is much smaller than hepatic blood flow (1500 mL/min). On the other hand, nifedipine, midazolam, triazolam, and indinavir are good substrate for CYP3A4 and are considered as moderate clearance drugs as their clearance is about half of hepatic blood flow, ranging from 400 to 700 mL/min. Verapamil, a good substrate of CYP3A4, has a clearance of 1000 mL/min and is categorized as high clearance drugs. Clinical studies have shown that treatment with rifampicin (a potent CYP3A4 inducer) caused significant but different magnitude of reduction in the AUC_{po} of these drugs. As shown in Table 14.1, the magnitude of the reduction in the AUC_{po} appears to be smaller for the low clearance drugs (3- to 8-fold) than that for moderate clearance drugs (9- to 24-fold) or high clearance drugs (30- to 50-fold) [4–16]. As shown in Table 14.1, high clearance drugs are more sensitive to CYP induction as compared to low clearance drugs. These observations are very similar to the simulations when parallel-tube model, but not well-stirred model, was employed (Fig. 14.1). In other words, simulations by parallel hepatic model, rather than well-stirred model, more accurately reflect the *in vivo* CYP induction-mediated drug–drug interactions.

CYP2C8 and CYP2C9 can also be induced by rifampicin. However, the effect of rifampicin on drugs that are predominately metabolized by CYP2C8 or CYP2C9 appears to be less significant compared to that on drugs metabolized by CYP3A4 (Table 14.2). Rifampicin treatment only caused three- to fourfold changes in the AUC_{po}

TABLE 14.1 Effect of Rifampicin on the Oral AUC of Drugs that are Metabolized Predominately by CYP3A4

^bFold induction: the ratio of AUC before and after rifampicin treatment.

^cμg h/mL.

of warfarin, which is metabolized predominately by CYP2C9 [17]. After the treatment with rifampicin at 600 mg twice daily for 4 days, the AUC_{po} of (*R*)-warfarin decreased from an average of 159–47 µg h/mL, while the AUC_{po} of (*S*)-warfarin decreased from 232 to 60 µg h/mL in healthy volunteers receiving an oral dose of racemic warfarin.

Rosiglitazone, an insulin-sensitizing agent, is eliminated mainly by CYP2C8 [22]. After the treatment of rifampicin 600 mg once daily for 6 days in healthy volunteers, the AUC_{po} of rosiglitazone decreased from an average of 2676–988 ng h/mL after an oral administration [18]. Glimepiride is a new sulphonylurea antidiabetic agent, which is eliminated mainly by CYP2C9 [23]. There was only a 1.5-fold decrease in the AUC_{po} of glimepiride after the treatment of rifampicin 600 mg once daily for 5 days [19]. Following an oral administration, the AUC_{po} of glimepiride decreased from 287 ng h/mL before the rifampicin treatment to 190 ng h/mL after the rifampicin treatment. Similarly, rifampicin has less profound effect on the AUC_{po} of gliclazide, glyburide, and glipizide, which are eliminated predominately via metabolism by CYP2C9 [20,21]. The magnitude of reduction in the AUC_{po} after the rifampicin treatment ranged from 1.3- to 2.9-fold for gliclazide, glyburide, and glipizide (Table 14.2).

All of the CYP2C8/CYP2C9 drugs listed in Table 14.2 can be classified as low hepatic clearance drug because their clearance value is less than 200 mL/min in humans. The relatively small changes in the AUC_{po} of these CYP2C8/CYP2C9 drugs after rifampicin treatment are consistent with the notion that the magnitude of reduction in the AUC_{po} after CYP induction tends to be lower for low hepatic clearance drugs compared to that for high hepatic clearance drugs. However, even for low hepatic clearance drugs, the effect of rifampicin appears to be less significant for CYP2C8/CYP2C9 drugs compared to CYP3A4 drugs. As shown in Tables 14.1 and 14.2, the changes in AUC_{po} were generally smaller for CYP2C8/CYP2C9 drugs (1.3- to 3.5-fold) than that for low clearance drugs of CYP3A4 (3.5- to 8-fold). The differences in the magnitude of AUC_{po} reduction between CYP3A4 drugs and CYP2C8/CYP2C9 drugs may be because of differential induction between different CYP genes by rifampicin, suggesting that the *CYP2C8* and *CYP2C9* genes are less sensitive to rifampicin as compared with *CYP3A4* gene.

^bFold induction: the ratio of oral AUC before and after rifampicin treatment.

^cµg h/mL.

The argument that *CYP2C8* and *CYP2C9* genes are less sensitive to rifampicin is supported by data from *in vitro* studies. In a study with human hepatocytes, the *CYP3A4* mRNA increased about 25-fold, while the *CYP2C8* and *CYP2C9* mRNA only increased 3- to 4-fold after incubation for 24 h with rifampicin [24]. In another study with cultured human hepatocytes, protein and activity of *CYP2C8* and *CYP2C9* were induced by 3- to 5-fold after rifampicin treatment, while the protein and activity of *CYP3A4* was induced by 10-fold after rifampicin treatment [25]. Similar observations of differential induction of CYP genes by rifampicin have been reported by other investigators [26,27].

14.2.4 Time- and Dose-Dependent CYP Induction

Enzyme induction is a slow regulatory process, involving gene transcription, replication of RNA, and biosynthesis of protein. Therefore, the CYP induction is expected to be a time- and concentration (dose)-dependent process. The time- and concentration-dependent induction of *CYP1A1* and *CYP1A2* by tetrachlorodibenzo-*p*-dioxin, (TCDD) has been demonstrated in studies using human splenic lymphocytes and colon carcinoma cell line LS180 [28,29]. In the human splenic lymphocytes and LS180, TCDD markedly induced mRNA, protein, and enzyme activity in a time- and concentration-dependent manner. In the LS180 cell cultures, maximal mRNA induction of *CYP1A1* and *CYP1A2* occurred between 6 and 24 h after the treatment with TCDD. *CYP1A1* protein reached to its maximum at 48 h, while the *CYP1A2* protein reached its maximum between 48 and 72 h. These results clearly suggest that there is a lag time between the mRNA translation and protein synthesis, reflecting an extra time required for protein synthesis.

Consistent with *in vitro* observations, time- and dose-dependent TCDD-mediated *CYP1A1/2* induction has also been demonstrated in rats *in vivo* [30]. The protein expression of *CYP1A1* and *CYP1A2* was induced in a dose-dependent manner in rats over a dose range of TCDD (0.01–30 µg/kg). The ED₅₀ for TCDD-induced *CYP1A1* and *CYP1A2* protein expression was estimated to be 0.22 and 0.4 µg/kg, respectively. Although a significant increase in the expression of TCDD-induced *CYP1A1* and *CYP1A2* protein was observed at 24 h, both *CYP1A1* and *CYP1A2* reached their maximal levels at 7 days following a single oral dose of TCDD (10 µg/kg). After reaching the peak, the protein level declined slowly via protein degradation. Even at 35 days after a single dose of TCDD administration, *CYP1A1* and *CYP1A2* protein still did not return to the basal levels. The persistence of the expression of TCDD-induced *CYP1A1* and *CYP1A2* protein may be related to the slow hepatic elimination of TCDD. Hepatic concentration of TCDD reached a maximum about 8 h after TCDD administration followed by a slow elimination with a half-life of approximately 10 days. A physiologically based pharmacokinetic model incorporated tissue retention of TCDD and its affinity binding to arylhydrocarbon receptor (AhR) has been successfully developed to describe the persistence of *CYP1A* induction in rats and mice for TCDD and its analogs [31–33].

In addition to TCDD, the time- and dose-dependent induction of *CYP1A1* and *CYP1A2* by omeprazole has been demonstrated in human hepatoma cell line HepG2 [34,35]. Consistent with *in vitro* observations, dose-dependent induction of *CYP1A1/2* caused by omeprazole has also been observed in humans *in vivo*. Induction of intestinal *CYP1A* by omeprazole was studied in six healthy volunteers [36]. In this study,

endoscopic tissue specimens were analyzed for mRNA and enzyme activity measured by deethylation of ethoxyresorufin before and after the treatment with omeprazole 20 mg/day for 1 week. Large interindividual variations of CYP1A induction were observed. The extent of CYP1A induction ranged from no change in one subject to a sixfold increase in another subject. The individual who did not initially respond (20 mg/day) had a marked increase in both mRNA and enzyme activity after receiving 60 mg of omeprazole daily for 1 week, suggesting that CYP1A induction is dose dependent. Similarly, dose-dependent induction of CYP1A2 by omeprazole has been demonstrated between 40 and 120 mg doses, as measured by ^{13}C -[N-3-methyl]-caffeine breath test [37]. In another clinical study, CYP1A2 was induced in poor metabolizers (PMs) of CYP2C19 but not in extensive metabolizers (EMs) after 7 days treatment with omeprazole at 40 mg/day [38]. Because that omeprazole is eliminated predominately by CYP2C19-mediated metabolism, the plasma AUC_{po} of omeprazole in PMs of CYP2C19 was approximately 5-fold higher than that in EMs after an oral dose of 40 mg. Therefore, the differential effect of omeprazole on CYP1A induction between PMs and EMs of CYP2C19 can be explained by concentration-dependent induction. Collectively, these results clearly demonstrate that omeprazole induces *CYP1A1* and *CYP1A2* genes in a concentration (dose)-dependent manner.

Cigarette smoking is known to induce CYP1A2 enzyme, and the smoking-induced CYP1A2 gradually returns to the basal level via protein degradation after cessation of smoking. In a clinical study, the degradation half-life of the smoking-induced CYP1A2 has been determined in heavy cigarette smokers after cessation of smoking [39]. This study was conducted with 8 men and 4 women who smoked 20 cigarettes or more per day. Subjects were phenotyped for CYP1A2 activity at 6, 4, and 1 days before smoking cessation and at 0, 1, 2, 3, 6, 8, 10, and 13 days thereafter by measuring caffeine clearance. The CYP1A2 activity decreased as a function of time, and a maximal decrease was observed at six or eight days after cessation. The degradation half-life of CYP1A2 activity was estimated to be about 36 h. Similar to the degradation half-life of CYP1A2 enzyme in humans, the degradation half-life of the Aroclor-induced CYP1A1 and CYP1A2 has been estimated to be 20 to 37 h, respectively, in rats [40,41].

Rifampicin is one of the most potent inducers of human *CYP3A4* gene. The time- and dose-dependent induction of CYP3A4 by rifampicin has also been demonstrated in primary cultures of human hepatocytes [42]. In human hepatocytes treated with rifampicin, the induction of CYP3A4 activity (measured by testosterone 6 β -hydroxylation) was concentration dependent, and the EC_{50} for rifampicin was estimated to be 0.3–0.5 μM [43]. The dose of rifampicin used in the treatment of tuberculosis is usually between 450 and 600 mg once daily [44]. In a clinical study, the effect of rifampicin on the pharmacokinetics of diazepam (a low hepatic clearance drug) was not significantly different between 600 and 1200 mg oral dose [45]. The AUC_{po} of diazepam decreased from an average of 4430–1040 ng h/mL after the treatment with rifampicin at 600 mg, while from an average of 4170–1130 ng h/mL after 1200 mg rifampicin. Similarly, the effect of rifampicin daily dose of 600, 900, and 1200 mg on the disposition of propranolol (a high hepatic clearance drug) was also not significantly different [46]. Together, these results suggest that the inductive effect of rifampicin at the dosage of 450–600 mg is probably near maximal. The notion of maximal inductive effect at 450–600 mg is further supported by the comparison of the EC_{50} and the systemic exposure of rifampicin at clinical dose. In a clinical study, the peak plasma concentration and AUC_{po} of rifampicin were 20 $\mu\text{g/mL}$ and 100 $\mu\text{g h/mL}$,

respectively, following an oral dose of 600 mg [47]. The peak concentration ($\sim 20 \mu\text{M}$) and average systemic exposure ($4\text{--}5 \mu\text{M}$; measured by $\text{AUC}/24\text{h}$) are much greater than the EC_{50} for rifampicin ($0.3\text{--}0.5 \mu\text{M}$).

Time-dependent CYP3A4 induction by rifampicin has also been demonstrated in humans. In a clinical study, the time course of the CYP3A4 induction was evaluated by measuring the steady state trough concentrations of verapamil before, during, and after a 12-day treatment with rifampicin 600 mg once daily [5]. The maximal effect of rifampicin on the CYP3A4 activity was observed at eight days after starting the rifampicin treatment and returned to the baseline activity about two weeks after discontinuing rifampicin treatment. The half-life for increase in CYP3A4 activity was estimated to be about 0.9 day for (*R*)-verapamil and 1.0 day for (*S*)-verapamil, and the half-life for decrease in CYP3A4 activity was 1.5 days for (*R*)-verapamil and 2.1 days for (*S*)-verapamil. It is reasonable to assume that the increase in CYP3A4 activity reflects mainly the synthesis of CYP3A4 protein and the decrease in CYP3A4 activity reflects mainly the degradation of CYP3A4 protein. If the assumption is valid, these results suggest that the process of protein degradation is somewhat slower than the process of protein synthesis.

Consistent with the half-life of CYP3A4 induction of approximately 1 day, a significant CYP3A4 induction was observed as early as 8 h after a single dose of rifampicin [48]. Nifedipine was given orally 8 h after a single dose of rifampicin (1200 mg) in healthy volunteers. The AUC_{po} of nifedipine decreased from an average of 573 ng h/mL before rifampicin treatment to 205 ng h/mL at 8 h after a single rifampicin treatment. Although the change in the AUC_{po} of nifedipine after 8 h (2.8-fold) after a single dose is much less than that after a seven days treatment (15.5-fold as shown in Table 14.1), a duration of 8 h is sufficient to induce a significant amount of CYP3A4 protein level leading to a significant increase in the activity of this enzyme.

14.3 EFFECTS OF CYP INDUCTION ON PHARMACODYNAMICS

For drugs whose elimination is cleared primarily by CYP-mediated metabolism, CYP induction will reduce the therapeutic efficacy as a result of a decrease of systemic exposure. In some cases, changes in drug dosage are required in order to attain and maintain a therapy during the initiation, maintenance, and discontinuation of the coadministration of a potent CYP inducer. In addition, CYP induction may create an undesirable imbalance between bioactivation and detoxification, leading to an increase in metabolite-induced toxicity. Although the research on the potential risk of CYP induction-mediated toxicity has received much less attention than the pharmacokinetic and pharmacological effects, there is increasing evidence that CYP induction could be a serious cause for drug-induced toxicity.

14.3.1 Effects of CYP Induction on Therapeutic Efficacy

Reduction in therapeutic efficacy caused by CYP induction is best exemplified by the rifampicin–cyclosporine interaction. Because of the treatment with immunosuppressive agents, there is a high incidence of tuberculosis among organ transplant recipients. In a retrospective study, analysis of the records of 880 renal transplant recipients in Turkey revealed that 36 patients were infected and developed tuberculosis after renal

transplantation [49]. In another study, a very high incidence of tuberculosis (42%) was reported among 305 renal transplant recipients in India [50]. Because rifampicin still remains as an effective antituberculosis agent, it is often concomitantly used with cyclosporine (or tacrolimus) in transplant recipients, and clinically significant drug interactions between rifampicin and cyclosporine have been reported. In a clinical study, treatment with rifampicin 600 mg once daily for 11 days caused a more than 3-fold decrease in the AUC_{po} of cyclosporine, presumably due to CYP3A4 induction [7]. Importantly, treatment with rifampicin had caused acute transplant rejection in patients treated with cyclosporine [51]. The acute transplant rejection is most likely because of significant reduction of cyclosporine exposure caused by rifampicin-mediated CYP3A4 induction. Similar to cyclosporine, an 18-day treatment with rifampicin 600 mg daily markedly reduced the AUC_{po} of tacrolimus (a good substrate of CYP3A4) by about 3-fold in patients [8]. Therefore, an increase in the tacrolimus dosage was required to attain the effective blood concentration of tacrolimus in order to avoid graft rejection in transplant recipients [52].

Warfarin–rifampicin interaction is also a good example for CYP induction-mediated reduction of drug efficacy. Warfarin, a prototypic CYP2C9 substrate, remains as the first line anticoagulant therapy. The unfavorable narrow range of therapeutic concentration makes warfarin prone to potentially life-threatening drug–drug interactions [53]. In a clinical study, the AUC_{po} of warfarin was decreased by about 3-fold after a 21-day treatment with rifampicin 600 mg daily [54]. The reduction of warfarin plasma concentration is believed to be due to the rifampicin-mediated CYP2C9 induction. Consistent with a threefold decrease in warfarin plasma concentration, rifampicin treatment caused a threefold decrease in the anticoagulant effect of warfarin. In a case report [55], a patient receiving concomitant rifampicin and warfarin to treat a mycobacterial infection and intraventricular thrombus, respectively, required a more than twofold increase in the dosage of warfarin to attain the therapeutic efficacy, measuring by international normalized ratio (INR). Because of temporal changes of enzyme level, the dose of warfarin should be reduced gradually after discontinuing rifampicin treatment to maintain a balance between therapeutic efficacy and adverse effect. A gradual 70% reduction in warfarin dosage over 4–5 weeks was necessary to maintain the therapeutic INR after rifampicin discontinuation [55]. In another case report, a 72-year-old patient taking warfarin was concurrently administered rifampicin for several months [56]. During this period, satisfactory anticoagulation was achieved only when a high dose of warfarin (20 mg) was given. After discontinuation of rifampicin therapy, warfarin dose was adjusted gradually, until the stabilization of the prothrombin time at warfarin 7.5 mg.

Because of narrow therapeutic index of antiarrhythmic agents, potential interaction with other drugs is of therapeutic importance in the clinical practice. Quinidine, a substrate of CYP3A4, is used for the treatment of cardiac arrhythmias. After 7 days of daily treatment with rifampicin 600 mg in 6 healthy volunteers, the AUC_{po} of quinidine decreased dramatically by 9-fold [13]. In another clinical study, a 7-day treatment with rifampicin 600 mg daily caused a 5-fold decrease in the AUC_{po} of quinidine [57]. Although no published studies or case reports have described the pharmacodynamic changes with respect to the quinidine–rifampicin interaction, it is likely that the interaction could be clinically significant. A clinically significant reduction in the QRS prolongation has been reported as a result of rifampicin–propafenone interaction. Propafenone, a sodium channel-blocking antiarrhythmic drug, is metabolized by CYP2D6 to 5-hydroxy-propafenone and by CYP3A4 to N-dealkylation metabolite

[58]. Both 5-hydroxy-propafenone and N-dealkylation-propafenone are active metabolites with activity as potent as the parent drug. The oxidative metabolites are subsequently eliminated by phase II metabolism, glucuronidation, and sulfation. The effect of rifampicin on the pharmacokinetics and pharmacodynamics of propafenone was studied in six EMs and six PMs of CYP2D6 [59]. After a 9-day rifampicin treatment (600 mg/day), the AUC_{po} of propafenone decreased from an average of $6.9\text{--}1.8\text{ }\mu\text{M h}$ in the EMs and from 54 to $16\text{ }\mu\text{M h}$ in PMs. Interestingly, rifampicin also affected the pharmacodynamics of propafenone in both EMs and PMs of CYP2D6. The maximum QRS prolongation decreased from 21% to 13% in EMs and from 15% to 9% in PMs. Since CYP2D6 is not inducible, the rifampicin's effect on the pharmacokinetic and pharmacodynamics of propafenone is probably due mainly to the CYP3A4 induction. However, interpretation of clinical consequences of propafenone by CYP induction would be somewhat complicated in this case because of the formation of active metabolites.

Similarly, the interaction between rifampicin and codeine is quite complex. Codeine is a widely used opiate analgesic agent that is converted through O-demethylation to morphine by CYP2D6 in humans [60,61]. Although the formation of morphine accounts for >10% of over all clearance of codeine, morphine is responsible for most of the analgesic effect of codeine. Unlike morphine which is eliminated mainly by UDP-glucuronosyltransferases (UGTs), codeine is metabolized by multiple enzyme systems, including CYP2D6, CYP3A4, and UGTs [62,63]. The effect of rifampicin on the pharmacokinetics and pharmacodynamics of codeine has been studied in EMs and PMs of CYP2D6 [63]. After treatment of rifampicin (600 mg/day) for 3 weeks, rifampicin had little effect on pharmacodynamics of codeine in PMs of CYP2D6. Because CYP2D6 is not inducible by rifampicin, it is expected that rifampicin will have no significant effect on the pharmacodynamics of codeine in EMs as well. Surprisingly, the codeine's pharmacodynamic effects were attenuated in EMs of CYP2D6 after rifampicin treatment. This is because that rifampicin significantly decreased the concentration of codeine through an increase in the clearance of the major elimination pathways of codeine, namely, CYP3A4-dependent N-demethylation and UGT-dependent glucuronidation, which can be induced by rifampicin. Thus, the conversion of morphine from codeine was significantly reduced in the EMs of CYP2D6 due to the decreased codeine concentration during rifampicin treatment. In addition to the decreased morphine formation, the elimination of the converted morphine can also be enhanced via glucuronidation by rifampicin-induced UGTs.

Morphine is eliminated exclusively by UGTs to form glucuronide-3-morphine and glucuronide-6-morphine in humans [64]. A significant drug interaction has been observed between morphine and rifampicin. In a clinical study, the serum concentrations of morphine, glucuronide-3-morphine, and glucuronide-6-morphine were measured before and after the treatment with rifampicin 600 mg once daily for 13 days [65]. There was only a moderate decrease in the serum concentrations of morphine after the treatment with rifampicin. The AUC_{po} and C_{max} of morphine, respectively, decreased from an average of 132 nM h and 34.5 nM before rifampicin treatment to 97 nM h and 18 nM after rifampicin treatment. Similarly, there was also a significant decrease in the AUC of glucuronide-3-morphine and glucuronide-6-morphine [65]. Although rifampicin treatment only caused a moderate decrease in concentrations of morphine and its active metabolite, a complete loss of analgesic effect of morphine was observed in these volunteers after the treatment of rifampicin.

The HIV protease inhibitors are used for the treatment of patients infected with HIV. Because of the increasing incidence of tuberculosis among patients infected with HIV, rifampicin is often concomitantly used with HIV protease inhibitors. Therefore, rifampicin-mediated CYP induction becomes a serious concern in the treatment of HIV infection [66]. After a 14-day rifampicin treatment (600 mg/day), both the AUC_{po} and C_{max} of saquinavir decreased by more than 4-fold in healthy volunteers [67]. Similarly, treatment with rifampicin (600 mg/day) for 7 days caused a 5-fold decrease in both the AUC_{po} and C_{max} of nelfinavir [68]. Significant reduction in the AUC_{po} and C_{max} of ritonavir and indinavir after the rifampicin treatment has also been reported [16,69]. Because the antiretroviral effect is highly dependent on the systemic exposures of the HIV protease inhibitors, the use of rifampicin is contraindicated to avoid treatment failure. In some cases, a dosage adjustment may be required to achieve the antiretroviral effect. For example, the dosage of efavirenz, a nonnucleotide transcriptase inhibitor, needs to be adjusted from 400 to 800 mg daily, when rifampicin is concurrently administered [70]. Interestingly, efavirenz is also a CYP3A4 inducer. In a clinical study, the AUC_{po} of indinavir was decreased by 35% when coadministered with efavirenz [71]. To compensate the efavirenz-mediated induction, the dosage of indinavir was suggested to increase from 800 mg 3 times daily to 1000 mg 3 times daily.

The effect of rifampicin on the CNS drug action has also been studied. A 5-day rifampicin treatment (600 mg/day) caused a more than 3-fold decrease in the AUC_{po} of zolpidem [11]. In parallel, a significant reduction in the effects of zolpidem was seen in all psychomotor tests (digit symbol substitution, critical flicker fusion test, and Maddox wing test). In another clinical study, rifampicin treatment at 600 mg daily for 5 days resulted in a 5.5-fold decrease in the AUC_{po} of zopiclone and a significant reduction in the hypnotic effects [12]. Similarly, a 5-day rifampicin treatment (600 mg/day) caused a 10- to 20-fold decrease in the AUC_{po} of midazolam and triazolam [14,15]. As a result of the substantial decrease in systemic exposure, both midazolam and triazolam are ineffective in patients taking rifampicin. Therefore, it is advisable to use hypnotic agents that are not predominantly metabolized by CYP3A4 during treatment with rifampicin.

14.3.2 Effects of CYP Induction on Drug-Induced Toxicity

Epidemiological and animal studies have suggested that many xenobiotics and drugs cause toxicity by generating reactive metabolites or reactive oxygen species [72–74]. CYP1A enzymes are known to be responsible for metabolic activation and detoxification of some xenobiotics, such as polycyclic aromatic hydrocarbons. Although it is highly controversial whether CYP1A induction is beneficial because of detoxification, or is detrimental because of metabolic activation forming reactive metabolites, there is increasing evidence that CYP1A induction could be a risk factor that may cause toxicity and cancer [75–77]. For example, cigarette smoking has been found to be associated with pulmonary and cardiovascular diseases and cancer via CYP1A induction [78–81]. Recently, *in vitro* and animal studies suggest that some xenobiotics exert their toxicity, not only by generating reactive metabolites but also by altering expression of specific genes through AhR activation [74,75].

Induction of CYP2E1 by ethanol is believed to be responsible for hepatotoxicity by generating oxidative stress species [82,83]. Rate of the formation of superoxide and hydrogen peroxide was significantly increased in microsomes from ethanol-treated rats, in which CYP2E1 was induced [84,85]. *In vitro* studies revealed that human CYP2E1 is

also capable of forming reactive oxygen intermediates and catalyzing lipid peroxidation in CYP2E1-expressed HepG2 cells [86]. There is an increasing body of evidence that ethanol-induced hepatotoxicity is linked to the increased production of oxidative stress species. For instance, the ethanol-induced hepatotoxicity has been shown to correlate with the expression levels of CYP2E1 as well as the elevated lipid peroxidation in rats [87]. Furthermore, treatment of diallylsulfide, an inhibitor of CYP2E1, prevented the elevation of lipid peroxidation and partially blocked the ethanol-induced hepatotoxicity. Similarly, anti-CYP2E1 IgG has been used to prevent the formation of reactive oxygen species after ethanol treatment in animals [88].

Hepatotoxicity caused by CYP2E1 induction in humans has been suggested [89]. A male subject was in the habit of consuming three glass of wine regularly with dinner. He stopped ingesting ethanol when he contracted influenza and began taking acetaminophen for treatment. Several days later, he had a complete liver failure. It is believed that the hepatotoxicity is due to an increased formation of reactive metabolite of acetaminophen, *N*-acetyl-*p*-benzoquinone imine (NAPQI) as a result of CYP2E1 induction caused by heavy alcohol drinking. *In vitro* studies with human liver microsomes have demonstrated that CYP2E1 can modulate the formation of NAPQI [90]. Interestingly, ethanol is able not only to induce but also to inhibit CYP2E1 activity [91]. On the basis of the dual effects of ethanol, Slattey *et al.* [89] have developed a kinetic model to explain the complex ethanol–acetaminophen interaction. Through the model simulations, it becomes clear that the time interval between the last consumption of alcohol and ingestion of acetaminophen is very important in terms of the risk of hepatotoxicity. If acetaminophen is taken in the morning because of a headache as a result of the heavy drinking the night before, there is a high risk of hepatotoxicity. This is because at the next morning after heavy drinking, the low level of ethanol concentration is insufficient to inhibit the formation of NAPQI in the liver where CYP2E1 enzyme activity was induced, resulting in an increased formation of the toxic metabolite. However, if acetaminophen and ethanol are taken together at the same time, the formation of NAPQI is not expected to increase because of the opposite effects of CYP2E1 inhibition and induction by ethanol.

In addition to CYP2E1, NAPQI can also be formed by human CYP1A2 and CYP3A4 [91,92]. Therefore, it has been suggested that CYP1A2 and CYP3A4 may also contribute to the acetaminophen-induced hepatotoxicity. The role of CYP1A2 in acetaminophen-induced hepatotoxicity has been studied in wild-type, *Cyp2e1*^(-/-), and *Cyp1a2*^(-/-) mice [93–95]. Following the administration of acetaminophen at 250 mg/kg, there was no significant differences in the severity of hepatotoxicity between *Cyp1a2*^(+/+) and *Cyp1a2*^(-/-) mice, as measured by serum alanine aminotransferase. In addition, there was no difference in the urinary metabolites excreted over a 24-h period, including those derived from glutathione (GSH) conjugation of the major reactive metabolite NAPQI of acetaminophen, between the *Cyp1a2*^(+/+) and *Cyp1a2*^(-/-) mice. With these results, the investigators concluded that CYP1A2 does not play a significant role in acetaminophen hepatotoxicity in mice. Consistent with the findings in mice, induction of human CYP1A2 appears to have little effect on the formation of the reactive metabolite NAPQI of acetaminophen. In a clinical study with EMs and PMs of CYP2C19, omeprazole was administered orally at 40 mg daily for 7 days [96]. A significant CYP1A2 induction was observed only in the PMs but not in EMs of CYP2C19. Despite induction of CYP1A2 activity in the PMs, there was no significant difference in the formation of thioether conjugates,

which are terminal metabolites of NAPQI. Therefore, CYP1A2 induction may not significantly contribute to the formation of NAPQI of acetaminophen.

The role of CYP3A enzymes in acetaminophen-induced hepatotoxicity has also been studied in pregnane X receptor (PXR)-null mice [97]. Pretreatment with pregnenolone-16 α -carbonitrile (PCN), a potent inducer of mice Cyp3a11, markedly enhanced acetaminophen-induced hepatotoxicity, as revealed by increased serum concentration of liver enzymes and hepatic centrilobular necrosis in wild-type mice but not in PXR-null mice following an intraperitoneal dose of acetaminophen (350 mg/kg). Furthermore, PCN treatment significantly increased the GSH-derived metabolites of NAPQI in wild-type mice but not in PXR-null mice. These results suggest that Cyp3a11 plays an important role in acetaminophen-induced hepatotoxicity in mice.

The role of CYP3A4 in acetaminophen-induced hepatotoxicity has also been studied in humans. In a clinical study, pretreatment with rifampicin (600 mg/day) for a week showed no effect on the urine recovery of thiol metabolites formed by conjugation of NAPQI with GSH, suggesting that the contribution of CYP3A4 to the formation of NAPQI of acetaminophen may be negligible in humans [98]. On the other hand, the urine recovery of the thiol metabolites formed by conjugation of NAPQI with GSH was decreased by 69%, and the formation clearance of NAPQI was decreased by 74% by pretreatment with disulfiram, a potent CYP2E1 inhibitor [98]. These results strongly suggest that CYP2E1, rather than CYP3A4, is the major enzyme responsible for the acetaminophen-induced hepatotoxicity in humans.

14.4 CONCLUSIONS

Although our understanding of CYP induction has advanced significantly over the past 10 years through the discovery of key nuclear receptors, much still remains to be learned about the molecular mechanisms of CYP induction. One of the unsolved issues is the wide interindividual variability in CYP induction. There are a large number of factors that could contribute to the variability, including genetic and environmental variables. The relative contribution between the genetic and environmental variables is not readily assessed due in part to the complexity of CYP induction and insufficiency of proper experimental tools. Another critical issue that may complicate the prediction and interpretation of CYP induction is the interplay between efflux transporters and CYP enzymes. Although there is now an increasing evidence to suggest the interplay between CYPs and efflux transporters because of a striking overlap in substrates and inducers with CYP enzymes and efflux transporters, our knowledge about this interplay is still very limited [99–102]. This is because it is very difficult to accurately estimate the relative contribution of CYP enzymes and transporters to drug absorption and disposition. This is particularly true for drug interactions that are caused by CYP and transporter induction.

Because of the complexity of the contributing factors, quantitative prediction of CYP induction is very difficult, if not impossible. Although numerous *in vitro* systems have been developed to assess CYP induction, these systems are only useful for semiquantitative assessment whether a new drug candidate has a potential for CYP induction. Information obtained from *in vitro* induction studies is still limited in its ability to predict whether there is a “probability” of induction-based drug interactions. If the *in vitro* data suggest that a drug candidate could have a potential for CYP induction,

clinical studies should be conducted earlier to assess the degree of induction. Therefore, the induction data obtained from *in vitro* systems should not serve as a “no-gos” decision for drug development without a proper clinical assessment. Finally, a point worth mentioning is that in many cases, the CYP induction-mediated drug interaction is manageable by adjusting dosage regimen.

15.1 SUMMARY

Changes in drug-metabolizing enzyme (DME) expression during development are substantial and can impact the risk of adverse drug events in the fetus and child. Individual hepatic DME ontogeny can be categorized into one of three groups based on their developmental trajectories. Class I enzymes, for example, FMO1 or CYP3A7, are expressed at their highest level during the first trimester and either remain at high concentrations or decrease during gestation, but are silenced or expressed at low levels within one to two years after birth. SULT1A1 and CYP3A5 are examples of class II DME that

are expressed at relatively constant levels throughout gestation and minimal changes are observed postnatally. ADH1C and CYP2C9 are typical of class III DME that are not expressed or are expressed at low levels in the fetus, usually during the second or third trimester. Substantial increases in enzyme levels are observed within the first one to two years after birth. Combined with our knowledge of changes in physiological factors during early life stages, knowledge regarding DME ontogeny has permitted the development of robust physiological-based pharmacokinetic models and an improved capability to predict drug disposition in pediatric patients.

In contrast to the dramatic changes in DME expression that occur in early life stages, modest if any changes in hepatic DME expression occur in the elderly. Thus, the well-documented decreases in clearance for many drugs observed in later life stages are more likely due to physiological changes, such as a loss of renal function, changes in body composition and size, and decreases in liver volume relative to body surface area.

This chapter provides an overview of age-dependent changes in DME expression patterns and discusses some implications of the data with regard to drug therapy. Common themes emerging from our current knowledge are also discussed. Finally, the chapter presents some future perspectives and highlights gaps in knowledge that will be important to advance this field.

15.2 INTRODUCTION

Past therapeutic misadventures leading to adverse drug events have provided ample evidence that pharmacokinetic factors in children differ substantially from adults. Often cited are the incidences of gray baby syndrome resulting from the administration of chloramphenicol to neonates at doses extrapolated from those found effective and safe in midaged adults [1]. Similarly, toxicity and death in premature infants were linked to the use of benzyl alcohol as a preservative in intravenous fluids [2]. Studies subsequently demonstrated that the immature expression of critical conjugating enzymes, resulting in impaired metabolism and clearance, was primarily responsible for both toxicities [3,4]. However, increased drug sensitivity is not universal in children versus adults. Young children are more resistant to acetaminophen toxicity relative to adults largely because of an increased capacity for sulfate conjugation [5].

Less well-studied, age-dependent changes in drug disposition in the elderly also has been an issue of concern. In general, the rate of drug clearance in elderly patients, particularly over the age of 70, is decreased, although it is less clear whether this is because of corresponding decreases in the expression of specific enzymes and/or physiological factors [6]. Never the less, combined with the facts that most therapeutics utilized in pediatric patients are used off-label [7] and the increased incidence of polypharmacy and risk of adverse drug–drug interactions in the elderly [6], the above observations have been major drivers to better understand mechanisms underlying life-stage-dependent changes in drug metabolism and disposition.

15.3 PHYSIOLOGICAL FACTORS IMPACTING AGE-DEPENDENT DRUG DISPOSITION

In addition to age-dependent changes in the expression of specific DMEs, several physiological parameters undergo changes during development and aging that impact

drug disposition (for recent reviews, see Refs 6 and 8). Intragastric pH is elevated in the neonate and elderly resulting in lower bioavailability of weakly acidic drugs. Also impacting drug absorption from the gastrointestinal tract, maturation of intestinal motor activity takes place during early infancy and then decreases in the elderly. The distribution of drugs can be impacted by age-dependent changes in body composition and changes in the major drug-binding plasma proteins [6,9].

Although the above physiological changes can be important, anatomical and functional changes in the liver and kidney have a quantitatively more important influence on pharmacokinetics. Hepatic organogenesis begins during the fourth week of gestation and progresses rapidly with the fundamental components of the liver being formed by the end of the first trimester. By 12 weeks, the smooth endoplasmic reticulum is developing and is present in large amounts by midgestation (see review by Ring *et al.* [10]). However, the ratio of liver to body mass also is considerably greater in infants and young children. This difference alone accounts for some of the developmental differences in drug metabolism between middle-aged adults and children [11,12]. Scaling by normalizing to a 70-kg individual using the 3/4 power allometric rule [$\text{Activity}_{70\text{kg}} = \text{Activity}/(\text{Weight}/70\text{kg})^{0.75}$] can be used to adjust for differences in liver size relative to body mass in pediatric versus middle-aged adult individuals see Ref. 13. Liver volume relative to body surface area further decreases in the elderly. For example, in a group of 14 individuals (9 females and 5 males) with a mean ($\pm$ SD) age of 28.8 ± 8.3 years, liver volume per unit of body surface area (mL/m^2) was 948 ± 109 versus 795 ± 153 in a group of 14 individuals (7 females and 7 males) with a mean ($\pm$ SD) age of 82.5 ± 7.1 years [14]. In an even larger study of 65 individuals between the ages 24 and 91 years, Wynne *et al.* [15] documented a 30% and 43% decrease in liver volume per body weight (mL/kg) in males and females, respectively, and a decrease in liver blood flow per body weight ($\text{mL}/\text{min}/\text{kg}$) of 43% and 55% in males and females, respectively.

More recently, there has been growing appreciation for the contribution of age-dependent changes in hepatic microsomal protein content to age-dependent changes in pharmacokinetics. Although highly variable, the average microsomal protein content of a 30 years old was observed to be 40 mg/g liver with a decline to 31 mg/g liver for the average 60 years old [16]. Extending these studies using a set of pediatric samples suggested an increase in microsomal protein content from a neonatal value of 26 mg/g liver to the maximum observed at age ~ 30 years [17]. Limited data would suggest even less microsomal content in the fetal liver [18]. Importantly, age-dependent changes in microsomal content during early life stages would have an opposite effect on drug disposition relative to the changes in liver size relative to body mass. However, the decrease in microsomal content in the elderly, combined with the decrease in both liver blood flow and liver volume relative to body weight, would have at least an additive negative impact on drug disposition in the elderly.

The maturation of kidney structure and function has a profound impact on those drugs that depend on renal clearance for the elimination and/or termination of pharmacological action (reviewed in Ref. 9). Nephrogenesis begins as early as 9 and is complete by 36 weeks gestation. However, vasoconstriction and reduced renal blood flow result in a substantially diminished glomerular filtration rate (GFR) in the term infant versus the middle-aged adult. At birth, there is a decrease in vascular resistance, as well as increases in cardiac output and renal blood flow, resulting in rapid increases in GFR. Despite these parturition-associated events, GFR is more tightly correlated

with postconceptional age than postnatal age, clearly suggesting that maturation of renal structure continues to influence GFR in the postnatal period and that mature GFR levels are not attained until approximately one year of age. Tubular secretion and reabsorption can also play an important role in renal drug clearance. At birth, the renal tubules are not yet mature and secretory and reabsorption transport activity is only 20–30% of adult values. Increases in activity to mature levels of tubular secretion occur over the first seven to eight months. Information on the ontogeny of specific renal transport enzymes in the human remains deficient and would greatly aid in our understanding of early life stage differences in drug response and risk for adverse events.

Age-dependent decreases in GFR are well documented in the elderly [19]. Normal mean GFR measured by inulin clearance decreases from ~ 120 mL/min/1.73 m² at age 40 years to ~ 65 mL/min/1.73 m² in men and 80 mL/min/1.73 m² in females at age 90 years. Thus, it is important to correct for these age-dependent changes in renal function for drugs eliminated by this route and, in particular, for drugs with a narrow therapeutic window.

The development of specific antibody and/or metabolic probes for many of the enzymes involved in drug metabolism, as well as improvements in detection methods and the availability of relatively large sets of tissue samples with dense coverage of critical age brackets, has allowed for numerous *in vitro* studies focused on drug metabolism ontogeny over the last decade. Furthermore, a greater understanding of the need for pediatric clinical trials combined with the knowledge and instrumentation to carefully determine fractional metabolic clearance has provided for a limited number of *in vivo* ontogeny studies. Although less well studied, this same approach has provided substantial information on potential DME expression changes in the elderly. Thus, we have a much better understanding of the expression trajectories for many of the metabolic factors impacting drug disposition as a function of age.

15.4 THE CYTOCHROME P450-DEPENDENT MONOOXYGENASES

The human cytochrome P450 enzyme superfamily (EC 1.14.14.1) is encoded by 59 functional genes which have been classified into 18 families and 42 subfamilies based on divergent evolution. Although they may have other roles, the function of drug metabolism is carried out by 23 enzymes belonging to families one through three. Other cytochrome P450s are involved in the synthesis and degradation of important endogenous signaling molecules. Necessary for monooxygenase activity, the drug-metabolizing cytochrome P450s interact with NADPH-dependent cytochrome P450 oxidoreductase, encoded by a single gene on chromosome 7q11.2 (*POR*), which shuttles the necessary reducing equivalents from its flavin-center to the cytochrome P450 heme protein.

15.4.1 Cytochrome P450 1A2 (CYP1A2)

Cazeneuve *et al.* [20] employed caffeine as a metabolic probe and observed an age-dependent change in the CYP1A2 metabolic pattern consistent with very low to absent expression in fetal and neonatal liver and onset of expression in tissues from infants (1.5–10 months postnatal age), but at levels that were 10-fold less than those observed

in adults. These results corroborated earlier *in vivo* results [21] that measured urinary caffeine metabolites. A CYP1A2 developmental trajectory in which expression was not observed until well after birth was confirmed by Sonnier and Cresteil [22] using methoxyresorufin as a probe substrate and western blotting with an anti-rat polyclonal CYP1A1 antibody. CYP1A2 was not detectable in fetal liver, but a progressive increase in catalytic activity and protein levels was observed in postnatal samples with neonates at 4–5% of adult levels, tissue from one- to three-month-old infants at 10–15% of adult levels, samples from 3- to 12-month-old children at 20–25% of adult levels, and samples from children aged one to nine years at 50–55% of adult levels. Diet can alter the rate of CYP1A2 maturation with formula-fed infants acquiring activity faster than breast-fed infants [23], but even under these conditions, CYP1A2 exhibits the most delayed developmental trajectory of the cytochrome P450s studied to date.

Several studies have evaluated theophylline or caffeine clearance in the elderly as a measure of CYP1A2 activity (reviewed in Refs 6 and 24). Although some studies suggested little or no change with increasing age, other investigators have reported a pattern wherein clearance is reduced from 25% to 30% in individuals aged 65–90 years versus individuals aged 20–40 years. Bebia *et al.* [25] evaluated the ratio of plasma paraxanthine to caffeine in adult men and women divided into three age brackets: 18–<35 ($N = 36$), 35–50 ($N = 53$), and >50–86 ($N = 67$) years. Most importantly, because this study design employed a plasma metabolic ratio and thus minimized the impact of physiological factors on disposition, the data and conclusion more accurately reflect CYP1A2 metabolic capacity. No age-related changes were observed between the three age brackets, suggesting no significant age-dependent decrease in CYP1A2 expression in the elderly and that previous observations of decreased theophylline or caffeine clearance were largely due to decreased renal function and other physiological factors.

15.4.2 Cytochrome P450 2A Subfamily (CYP2A)

The human *CYP2A* gene family consists of three members, CYP2A6, 2A7, and 2A13. CYP2A6 catalyzes the 7-hydroxylation of coumarin [26] and the oxidation of nicotine [27], the former often used as a probe substrate for CYP2A6. CYP2A13 exhibits high activity toward the oxidation of the tobacco-specific procarcinogen, 4-(methylnitrosoamino)-1,-(3-pyridyl)-1-butanone [28]. CYP2A7 appears to be a functional pseudogene [26,29]. CYP2A6 and 2A13 exhibit tissue-specific expression patterns, largely restricted to the liver [30] and nasal mucosa [28], respectively. Developmental expression studies were consistent with the absence of CYP2A in human fetal liver, although protein expression (presumably CYP2A6) was readily detectable in adult liver [31,32] and as early as 17 weeks after birth [33]. Thus, hepatic CYP2A6 expression appears to be largely a postnatal event, although the exact developmental trajectory remains unknown.

Despite its importance in the metabolic activation and disposition of nicotine, there have been few reports on any potential CYP2A expression changes in the elderly. Sotaniemi *et al.* [34] reported that urinary 7-hydroxycoumarin as a percent of coumarin dose decreased by ~30% in individuals aged >65 years ($N = 10$) relative to individuals aged <25 years ($N = 10$), consistent with a significant decrease in CYP2A6 metabolic capacity in elderly patients. However, the sample size of the study population was insufficient to determine a more precise, age-dependent trajectory and furthermore,

these data do not allow one to differentiate between age-dependent changes in CYP2A6 expression and loss of renal function.

15.4.3 Cytochrome P450 2B6 (CYP2B6)

Croom *et al.* [35] evaluated the CYP2B6 developmental trajectory in 217 human liver samples from donors ranging in age from 10 weeks gestation to 17 years. CYP2B6 protein was detectable in 75% of the samples overall, but a progressive increase in the fraction of samples with detectable protein increased from 64% in the fetal samples to 95% in the samples from donors aged >10 years. There was a small, but significant twofold increase in protein levels immediately after the neonatal period, but otherwise, CYP2B6 expression levels changed little as a function of age. Changes in CYP2B6 expression in the elderly, if any, are unknown.

15.4.4 Cytochrome P450 2C Subfamily (CYP2C)

Encoded by four genes, *CYP2C8*, *2C9*, *2C18*, and *2C19*, clustered within an ~500 kbp locus on chromosome 10q24, the CYP2C enzymes accounts for ~18% of total adult liver cytochrome P450 [30] and the oxidative metabolism of 30% of clinically relevant drugs [36]. CYP2C9 is the highest expressed member of this family in adult liver, followed by CYP2C19 and 2C8 [37]. CYP2C9 substrates include warfarin, phenytoin, diclofenac, ibuprofen, tolbutamide, losartan [38], and indomethacin [39], while CYP2C19 substrates include omeprazole [40] and mephenytoin [41]. A single study by Tateishi *et al.* [42] is consistent with CYP2C8 expression increasing in the perinatal period, although this conclusion is based on a limited number of tissue samples. Nothing is known regarding hepatic CYP2C18 ontogeny or the ontogeny of any CYP2C enzymes in extrahepatic tissues. In contrast, the common use of several CYP2C9 substrates for pediatric indications [43–45], the activity of these enzymes in converting arachidonic acid to known signaling molecules [46,47], and an association between elevated CYP2C expression and sudden infant death syndrome [48], have stimulated several investigators to explore the ontogeny of hepatic CYP2C9 and 2C19.

Early studies on CYP2C hepatic ontogeny reported conflicting results on fetal expression. Maenpaa *et al.* [49] reported detectable protein in 11 of 17 fetal liver samples that likely was CYP2C9. In contrast, Treluyer *et al.* [50] failed to detect any CYP2C protein in 55 fetal liver samples. Total CYP2C protein levels that were 4–5% of those observed in adults were detectable in 11 liver samples from newborns aged less than one day, but rapidly increased to 22–30% of adult values in postnatal samples greater than one day, but aged less than one year. Tolbutamide hydroxylase activity generally correlated well with protein levels in these same liver samples, consistent with the majority of the measured protein representing CYP2C9. Koukouritaki *et al.* [51] more recently characterized both CYP2C9 and 2C19 developmental trajectories in a bank of 237 human liver samples using both activity assays (diclofenac 4-hydroxylase and (*S*)-mephenytoin 4'-hydroxylase, respectively) and immunoblotting. Although detectable in 80% of first and second trimester samples, CYP2C9 levels were only 1% of reported adult values [30,52]. CYP2C9 expression levels increased to 10% of adult levels in third trimester samples. Although mean CYP2C9 expression levels increased to 25% of reported adult levels in postnatal samples from birth to five months

of age, this metric is somewhat misleading. Samples from this age bracket exhibited large interindividual differences with ~50% of the samples having CYP2C9 levels that ranged in values no different than those observed in the third trimester, while the remaining 50% exhibited values as high as those observed in postpuberty samples; data that are consistent with an earlier phenytoin pharmacokinetic report [43]. Less interindividual variation was observed in tissue samples from donors ranging in age from 5 months to 18 years and mean protein levels were ~50% of adult values. In all instances, good correlation was observed between measured CYP2C9 protein levels and diclofenac 4-hydroxylase activity. Although the failure to observe CYP2C9 expression at adult levels is consistent with the study by Treluyer *et al.* [50] and suggests a late CYP2C9 maturation, this conclusion is inconsistent with pediatric pharmacokinetic studies wherein metabolic ability in children aged over one year is no different than that in adults [53,54]. This apparent discrepancy is likely explained by developmental changes in the liver size to body weight ratio, as illustrated by Takahashi *et al.* [55].

Unlike CYP2C9, CYP2C19 was detectable in all fetal liver tissue samples examined by Koukouritaki *et al.* [51] at levels that were 10–20% of those observed in adults and did not change with increasing gestational age. Furthermore, there was no apparent change in CYP2C19 levels at birth, but rather, a near linear increase over the first five months to levels that were 50–75% of those observed in adults. Thereafter, enzyme levels indistinguishable from adult levels were observed. This developmental trajectory was consistent with the (*S*)-mephenytoin 4'-hydroxylase activities observed in these same samples. Interestingly, a comparison of CYP2C9 and 2C19 levels in individual samples revealed that CYP2C19 is the dominant prenatal CYP2C enzyme in most individuals with a transition to CYP2C9 as the dominant postnatal enzyme shortly after birth.

The prevalent use of antiepileptic and antithrombosis drugs in the elderly and the importance of CYP2C enzymes in the disposition of these drug classes have been an impetus for the evaluation of age-dependent CYP2C changes in the aged. Conflicting data have been reported on the differential clearance of phenytoin, a CYP2C9 substrate, between middle-aged adults and the elderly. For example, Bach *et al.* [14] reported a significant 25% decrease in the clearance of unbound phenytoin normalized to liver volume between younger subjects (mean age of 29 years) versus elderly subjects (mean age of 83 years), while Perucca *et al.* [56] failed to find any age-dependent effects in similar populations. Consistent with the data reported by Bach *et al.* [14], estimation of an initial warfarin dose in individuals of 45 and 85 years of age, but otherwise of identical sex, genotype, body weight, and state of polypharmacy demonstrated a 25% decrease in older subjects (<http://www.warfarindosing.org>). However, none of these studies or examples differentiates between the contributions of physiological factors and actual CYP2C9 expression. Measurement of CYP2C9 (cytochrome P450₉) protein levels *in vitro* in 54 liver samples from donors ranging in age from 9 to 89 years failed to identify any age-dependent changes in expression [57], consistent with observed decreases in the clearance of CYP2C9 substrates being largely due to physiological changes, not metabolic capacity.

In contrast to CYP2C9, there is evidence for a decrease in CYP2C19 expression in the elderly relative to middle-aged adults. Early studies documented a significant 36 (female) to 50% (male) decrease in the clearance of unbound diazepam in individuals aged 61–84 years versus those aged 21–37 years [58]. Similar age-dependent decreases in clearance were reported for omeprazole [59]. Supporting a

role for decreased CYP2C19 expression contributing to the observed decrease in clearance, Bebia *et al.* [25] reported a 30–40% decrease in the ratio of urinary 4-hydroxymephenytoin to mephenytoin between individuals aged <35 and >50 years. Similar to what is observed during early life stages, the regulation of CYP2C9 and 2C19 appears substantially different in later life stages.

15.4.5 Cytochrome P450 2D6 (CYP2D6)

CYP2D6 accounts for <2% of total adult hepatic cytochrome P450 [30], yet catalyzes the oxidation of ~12% of clinically relevant drugs [36]. Substrates include propafenone [60], paroxetine [61], risperidone [62], codeine [63], and dextromethorphan [64]. These latter two reactions have been used as CYP2D6 phenotypic probes, dextromethorphan O-demethylation being particularly useful in pediatric studies. *CYP2D6* also is highly polymorphic with over 80 alleles identified to date, including several relatively common complete loss or reduced function variants, as well as copy number variants with increased activity [65].

Although fetal CYP2D6 was reported as undetectable in an early study by Ladona *et al.* [66], a much more extensive study by Treluyer *et al.* [67] reported CYP2D6 transcripts, protein, and dextromethorphan O-demethylase activity that was at least 5% of adult values in approximately one-third of the fetal samples <30 weeks of gestational age. The number of fetal samples with detectable CYP2D6 increased to nearly 80% in tissue from donors >30 weeks of gestational age, but maximum levels were not increased relative to the <30-week gestational age bracket. Beginning at one week after birth, a steady increase in CYP2D6 protein levels was observed such that neonates greater than one week of age exhibited mean CYP2D6 levels 30% of adults and infants up to five years of age, 70% of adults. There was a close correlation between CYP2D6 protein and mRNA levels in adult samples ($r^2 = 0.95$, $P < 0.005$), but not in fetal, newborn or infant samples, suggestive of a translational control mechanism overlying transcriptional regulation.

Blake *et al.* [68] employed a longitudinal study design measuring dextromethorphan O-demethylase activity in an overnight urine sample to assess CYP2D6 phenotype in 193 infants at 0.5, 1, 2, 4, 6, and 12 months after birth. Although interindividual dextromethorphan O-demethylase activities varied nearly 1000-fold, a clear correlation between activity and an assigned genotype-based CYP2D6 activity score was observed that did not change during the study period. These data are consistent with phenotype and genotype concordance by two weeks of age, which contrasts to the previous *in vitro* study [67]. A more recent *in vitro* evaluation of CYP2D6 ontogeny presented data more consistent with the above *in vivo*, longitudinal study [69]. Low levels of CYP2D6 activity and protein that did not exceed 5% of adult values were present in fetal samples and the fraction of positive samples increased with increasing gestational age. However, CYP2D6 activity and protein levels in samples greater than one week of postnatal age were no different than those observed in adults. Thus, CYP2D6 rapidly matured to an adult expression pattern shortly after birth. Consistent with this conclusion, stepwise linear regression analysis of factors contributing to CYP2D6 specific content revealed only increasing gestational age as important in fetal samples while both increasing postnatal age and haplotype were important in postnatal samples.

There is no evidence for significant changes in CYP2D6 expression in the elderly versus middle-aged adults, despite reported decreases in clearance of

CYP2D6 substrates in the elderly (reviewed in Ref. 24). Evaluating urinary 4-hydroxydebrisoquine/debrisoquine ratios in individuals <35 years of age, 35–50 years of age, and >50 years of age, no differences were observed among the different age brackets and no correlation was observed with body mass index, creatinine clearance, smoking, or alcohol intake [25]. Similarly, an evaluation of the urinary ratio of dextromethorphan to dextrorphan in a group of middle-aged (mean $\pm$ SD = 55.8 ± 5.6) versus elderly (mean $\pm$ SD = 76.2 ± 7.0) women failed to show any difference.

15.4.6 Cytochrome P450 2E1 (CYP2E1)

CYP2E1 accounts for ~7% of total hepatic cytochrome P450 in the adult liver [30] and is involved in the oxidative metabolism of about 2.5% of clinically relevant drugs [36], including acetaminophen [70], halothane [71], and chlorzoxazone [72].

The human hepatic CYP2E1 developmental trajectory was first reported by Vieira *et al.* [73], who evaluated enzyme content, chlorzoxazone hydroxylase activity, and relative transcript levels. Epigenetic regulatory mechanisms also were explored. CYP2E1 protein was undetectable in fetal samples, but was readily detectable in newborn samples at levels ~10% of adult values. Thereafter, a steady increase in CYP2E1 levels was observed such that by one year of age, protein levels and activity were essentially equivalent to adults. CYP2E1 protein levels and catalytic activity were closely associated as a function of age ($r^2 = 0.778$, $P < 0.001$), but neither correlated with transcript levels. DNA methylation at sites flanking exon 1 appeared important for controlling CYP2E1 ontogeny [74].

The inability to detect fetal hepatic CYP2E1 expression was consistent with some more limited studies [75–78], but contrasted with others [79–81]. This apparent controversy was resolved by an exhaustive study by Johnsrud *et al.* [82]. Although CYP2E1 was undetectable in first trimester fetal liver samples, it was present in 40% and 80% of second and third trimester samples, respectively. These data are consistent with nearly all previous reports. Studies reporting an absence of fetal liver CYP2E1 protein content utilized samples from the first or second trimester, while studies reporting the presence of fetal liver CYP2E1 utilized samples from the late second or third trimester period. Johnsrud *et al.* [82] also demonstrated that postnatal hepatic CYP2E1 increased slowly after birth, attaining a median level ~20% of that in the adult in the neonatal period, 50% of that in adults between 31 and 90 days after birth, and values equivalent to adults in samples from donors older than three months of age. Increasing postnatal age plus the presence of at least one copy of the *CYP2E1*1D* allele (a promoter polymorphism linked to increased gene expression in obese individuals and individuals consuming alcohol [83]), and ethnicity were all associated with greater CYP2E1 expression.

Several studies have documented minimal if any changes in the pharmacokinetics of CYP2E1 substrates in the elderly versus middle-aged adult (reviewed in Ref. 24). However, Bebia *et al.* [25] demonstrated a substantial increase in the urinary ratio of 6-hydroxychlorzoxazone to chlorzoxazone when comparing individuals <35, 35–50, and >50 years of age. In men and in comparison to the youngest group, the ratio increased by 47% in the middle-aged group and by 81% in the eldest group. In women, there was no change in the middle-aged group, but a similar 87% increase in the eldest group. Thus, these data would support a sexually dimorphic, age-dependent increase

in CYP2E1 metabolic capacity that would largely compensate for the decrease in physiological factors impacting drug clearance in the elderly.

15.4.7 Cytochrome P450 3A Subfamily (CYP3A)

The CYP3A subfamily consists of four genes, *CYP3A4*, *3A5*, *3A7*, and *3A43*, located at an ~270 kbp locus on human chromosome 7q21.1. CYP3A43 has minimal, if any, drug-metabolizing activity and is expressed at low levels where detectable. As such, this enzyme is not discussed further. In contrast, the remaining CYP3A members are collectively the most abundant members of the hepatic cytochrome P450s and account for nearly 46% of clinically relevant oxidative drug metabolism [36]. Despite sharing at least 85% sequence identity, CYP3A4, 3A5, and 3A7 exhibit considerable differences in both substrate specificity and patterns of expression. CYP3A4 comprises 10–50% of total cytochrome P450 in adult liver [30] and also exhibits high intestinal expression levels [84]. In both liver and intestine, CYP3A5 can be expressed at levels similar to CYP3A4, or even exceed them, subject to the presence of the *CYP3A5*1* allele [85,86]. CYP3A7 is the dominant enzyme in fetal liver, but can represent 10–40% of total CYP3A content in the adult liver and intestine, dependent on the presence of the *CYP3A7*1 C* allele [87].

Komori *et al.* [76] were the first to report age-dependent CYP3A expression using oligonucleotide probes specific for CYP3A7 (cytochrome P450 HFL) and CYP3A4 (cytochrome P450 NF). A strong CYP3A7 hybridization signal was observed using fetal, but not adult liver RNA, while the opposite pattern was observed with the CYP3A4 probe. In a separate study, CYP3A5 protein was shown to be expressed in a limited number of fetal and postnatal liver samples with no apparent age correlation [52]. Data supporting CYP3A-dependent fetal liver metabolic activity was obtained by evaluating the N-demethylation of codeine and dextromethorphan [66]. However, the interpretation of these data is complicated by the overlapping substrate specificities of the CYP3A enzymes. Although CYP3A4 has the greatest dextromethorphan N-demethylation activity, below a substrate concentration of 1 mM, both CYP3A7 and 3A5 exhibit activities 33% and 17%, respectively, of that exhibited by CYP3A4 (Pearce RE, Leeder JS. Children's Mercy Hospital, Kansas City, MO, personal communication). Yang *et al.* [88] demonstrated the presence of CYP3A-dependent activity and protein in early fetal hepatic tissue as early as 7–8.5 weeks gestation, but no immunoreactive protein in heart, lung, brain, or kidney. Amplification of CYP3A transcripts and sequence analysis provided strong evidence for CYP3A7 and to a lesser extent, CYP3A5, but not CYP3A4 in these fetal samples. Subsequent studies also demonstrated CYP3A7-dependent imipramine N-demethylation [89] and retinoic acid 4-hydroxylation [90] in fetal liver tissue. Other groups have demonstrated temporal-specific CYP3 expression at the transcript level consistent with these results [91,92]. These early studies clearly demonstrated a largely fetal liver-specific expression of CYP3A7 and postnatal expression of CYP3A4, while CYP3A5 appeared to be expressed in a limited number of hepatic samples during both life stages. However, the dynamics of the transition between CYP3A7 and 3A4 remained unknown.

Lacroix *et al.* [93] was the first to more fully characterize CYP3A7 and 3A4 developmental trajectories. Equal levels of total CYP3A protein expression were observed in all age brackets. In contrast, a CYP3A4-specific hybridization probe revealed fetal CYP3A4 transcripts that were 10% of adult levels in samples <30 weeks gestational

age, increasing to 20% of adult levels in fetal samples >30 weeks gestational age. Transcript levels 30–60% of adult values were present within one week after birth. Dehydroepiandrosterone (DHEA) 16 α -hydroxylation and testosterone 6 β -hydroxylation were subsequently used as semiselective phenotypic probes for CYP3A7 and 3A4, respectively. DHEA 16 α -hydroxylase activity ranged from 0.48 to 1.31 nmol/min/mg microsomal protein in fetal and neonatal samples up to 7 days after birth, but then declined steadily to 0.56 pmol/min/mg microsomal protein in neonates 8–28 days after birth, 0.34 nmol/min/mg microsomal protein in infants aged 1–3 months, 0.17 nmol/min/mg in children aged from 3 to 12 months, and finally to 0.07 nmol/min/mg microsomal protein in adult tissue samples. In contrast, testosterone 6 β -hydroxylase activity was only 0.004–0.008 nmol/min/mg microsomal protein in fetal samples. Activity rose steadily after birth to 0.012–0.015 nmol/min/mg microsomal protein in neonates aged up to seven days, 0.035–0.052 nmol/min/mg microsomal protein in neonates and infants aged from eight days to one year, and reached adult levels of 0.120–0.130 nmol/min/mg microsomal protein in children aged greater than one year. However, the possible contribution of CYP3A5 to any of these activities was not evaluated. A somewhat similar approach was taken by Stevens *et al.* [94], but using differential hydroxylation of DHEA at the 7 β - and 16 α -positions as probes for CYP3A4 and 3A7, respectively, and a multiple linear regression model developed using different ratios of recombinant CYP3A4 and 3A7 enzymes. In addition, CYP3A5 levels were determined immunologically. Consistent with earlier studies, CYP3A5 protein was observed in approximately 50% of all samples (6.0 ± 5.2 pmol/mg microsomal protein for those samples with detectable protein) with no age-dependent change. CYP3A7 was expressed at high but variable levels (289.5 ± 103.7 pmol/mg microsomal protein) in all fetal samples examined while CYP3A4 was present in <50% of the samples at levels nearly 100-fold less than CYP3A7 (3.4 ± 2.6 pmol/mg microsomal protein). After birth, there was an ~50% decline in neonatal CYP3A7 enzyme levels while little or no change was observed in CYP3A4 levels. In infants, between 30 days and 1 year of age, CYP3A7 levels again decreased by nearly fivefold while CYP3A4 levels increased modestly. In contrast to the earlier report by Lacroix *et al.* [93], CYP3A4 levels in children aged between 1 and 10 years remained well below adult levels (13.1 ± 15.5 pmol/mg microsomal protein, $n = 22$ vs 128.9 ± 99.9 pmol/mg microsomal protein, $n = 11$), although the data on CYP3A7 were consistent with an observed decrease to 3.3 ± 4.8 pmol/mg microsomal protein ($n = 22$). Thus, these data would suggest that in many individuals, CYP3A7 remains the dominant CYP3A enzyme in children up to one year after birth and that CYP3A4 expression increases steadily, but does not reach adult levels until well after one year of age. These conclusions regarding CYP3A4 postnatal ontogeny are consistent with an *in vivo*, longitudinal dextromethorphan *N*-demethylase study [68,95], as well as a metabolic study of amprenavir metabolism in fetal and postnatal liver samples [96]. Furthermore, the variable, but high levels of CYP3A7 expression in fetal liver is consistent with a report by Leeder *et al.* [97] in which mean CYP3A7 mRNA and protein levels were determined to be $14,200 \pm 15,000$ transcripts/ng total RNA and 234.8 ± 123.1 pmol/mg microsomal protein, respectively, in 54 fetal liver samples (11–32 weeks of gestational age). Protein levels correlated well with testosterone 2 α - and DHEA 16 α -hydroxylation activities. This same group also demonstrated significant correlations between NR1I2 (pregnane X receptor) and NR1I3 (constitutive androstane receptor) expression and both CYP3A7 fetal liver and CYP3A4 postnatal liver expression [98], consistent with the known role each of these nuclear receptors

have in regulating the expression of these genes. Yet the degree of association also clearly indicated the involvement of other factors.

The potential clinical implications of the CYP3A7/3A4 transition is illustrated by studies on the pharmacokinetics and pharmacodynamics of cisapride, a gastroprokinetic agent that was commonly used in pediatric patients presenting with feeding intolerance, apnea, and bradycardia associated with gastroesophageal reflux. Owing to a higher than acceptable incidence of drug-induced arrhythmia in adult patients, cisapride was removed from the market and used only through a limited access program for specific diseases, including feeding intolerance in neonates. However, a prospective study in this latter patient population demonstrated a significant increase in QT prolongation not associated with adult risk factors [99]. Given the evidence that cisapride is metabolized primarily by CYP3A4, but not by CYP3A5 or CYP3A7 [100], it was hypothesized that neonates would show deficient metabolic ability [101]. Consistent with this hypothesis, cisapride metabolism was only detectable in four of seven microsomal preparations from fetal or neonatal livers aged less than seven days and was low in those preparations that did show activity. The hypothesis was further confirmed by the *in vivo* study reported by Kearns *et al.* [102] in which the cisapride terminal elimination rate constant was shown to increase ~10-fold between 30 and 52 weeks postconceptional age. Other kinetic parameters also were consistent with compromised cisapride metabolic clearance in premature and term neonates. Thus, the differential substrate specificity of CYP3A4 and CYP3A7 combined with the developmental transition between these two enzymes can have a significant impact on the risk for adverse drug reactions in neonatal patients, particularly those born prematurely.

Because of its promiscuous drug-metabolizing activity and the potential for drug–drug interactions, there have been several studies evaluating possible changes in CYP3A4 expression in the elderly. Cotreau *et al.* [103] published an exhaustive review of numerous pharmacokinetic studies, some of which showed modest decreases in the clearance of CYP3A4 substrates. However, no age-dependent changes in midazolam clearance, a preferred CYP3A4 probe substrate, were observed between either young (mean age, 26 years) and elderly (mean age, 72 years) women or young (mean age, 27 years) and elderly (mean age, 70 years) men [104]. Similarly, there were no differences in results from an erythromycin breath test between individuals aged 20–60 years and 70–88 years [105]. Consistent with these *in vivo* results, no changes in CYP3A4 specific activity were observed in liver microsomes isolated from young versus elderly donors [106,107].

15.5 FLAVIN-CONTAINING MONOOXYGENASES (FMO)

The flavin-containing monooxygenases (FMO) family of enzymes (EC 1.14.13.8) is important for the oxidative metabolism of a wide variety of therapeutics containing nucleophilic nitrogen-, sulfur-, selenium-, or phosphorous-heteroatoms. Common substrates include tamoxifen, itopride, benzydamine, olopatidine, and xanomeline [108]. Eleven human *FMO* genes have been identified, although seven (*FMO6P-11P*) are pseudogenes. The FMO enzymes active in drug metabolism include FMO1, 2, and 3 [108].

Evidence for a developmental transition between human hepatic FMO1 and FMO3 was first reported by Dolphin *et al.* [109]. FMO1 and FMO3 mRNA levels were

quantified in individual fetal liver, kidney, lung, and brain and adult liver, kidney, and lung tissue samples from donors of unspecified ages. Although considerable interindividual variability was observed, FMO1 transcripts were the most abundant in fetal liver and kidney, but were only present at low levels in lung and brain. In the adult, FMO1 transcripts only were observed in the kidney. FMO3 transcripts were present at low levels in the fetal liver and lung, but not in kidney. In contrast, FMO3 transcripts were most abundant in the adult liver and also were expressed at low levels in the kidney and lung. The restriction of FMO1 expression to the fetal liver was confirmed by Yeung *et al.* [110] using immunological approaches to measure FMO1 protein levels in fetal and adult liver, and adult kidney and small intestine. Mean FMO1 levels of 14.4 ± 3.5 pmol/mg microsomal protein were observed in fetal liver, but expression was not detected in adult liver. FMO1 protein levels were highest in the adult kidney, 47 ± 9 pmol/mg microsomal protein, but also were present at significant levels in the adult small intestine (2.9 ± 1.9 pmol/mg microsomal protein). High levels of FMO1 expression in the adult kidney also were reported by Krause *et al.* [111]. Both of these studies are consistent with the earlier studies measuring transcript levels [109].

Although the studies by Dolphin *et al.* [109] and Yeung *et al.* [110] supported the concept of a developmental transition between human hepatic FMO1 and FMO3, several questions remained unanswered, including the time frame of the transition, whether or not coordinate regulation of both genes is involved, and whether there were interindividual differences in the timing of the FMO1/FMO3 transition? To address some of these questions, Koukouritaki *et al.* [112] quantified FMO1 and FMO3 protein levels in 240 human liver samples representing ages from 8 weeks gestation to 18 years after birth. This study revealed that hepatic FMO1 expression was largely limited to the fetus and that the highest level of expression (mean $\pm$ SD = 7.8 ± 5.3 pmol/mg microsomal protein) was observed at ages <15 weeks. FMO1 expression was detectable in 96% of the samples examined within this age bracket. FMO1 protein levels subsequently declined by ~50% in each subsequent trimester and expression was essentially silenced within three days after parturition in a birth-dependent process, rather than a gestational age-dependent process. Furthermore, the percentage of samples with detectable FMO1 decreased by 10% in the second trimester, 30% in the third trimester, and by 84% during the first three days after birth. FMO3 expression was detectable at low levels in about 15% of first trimester fetal liver samples, but expression was nondetectable throughout the remaining gestational period. Low FMO3 expression levels (1.1 ± 3.3 pmol/mg microsomal protein) also were observed in ~25% of the neonatal liver samples. However, it was only after 1 month and before 10 months of age that detectable FMO3 was observed in most samples with mean levels of 4.7 ± 5.9 pmol/mg microsomal protein. These data suggested birth is necessary, but not sufficient for the onset of FMO3 expression. FMO3 protein levels ~50% of adult values were observed in tissue samples from individuals aged between 10 months and 11 years. In postpuberty tissue samples up to 18 years, a gender-independent, near linear increase in FMO3 expression was observed to levels approaching adult values (26.9 ± 8.6 pmol/mg microsomal protein). The above studies suggest that not only is the ontogeny of hepatic FMO1 and FMO3 regulated independently, but that the ontogeny of FMO1 itself is regulated differently in different tissues. Support for this supposition has been reported by several laboratories. Zhang and Cashman [113] described FMO transcript levels in human brain as a function of age and demonstrated a decline in FMO1 mRNA levels in tissues from 18 to 21 weeks gestation donors through 15–40 years after birth. In

contrast, FMO2 and FMO3 expressions were unchanged. FMO1 transcripts also were present at relatively high levels in both fetal and adult nasal mucosa [114]. Consistent with the observed tissue-specific FMO1 developmental trajectories, Shephard *et al.* [115] demonstrated that FMO1 expression in kidney, small intestine, and fetal liver is regulated by the use of different promoters combined with alternative splicing.

Chung *et al.* [116] reported a decrease in FMO3 activity in individuals over the age of 30 years relative to 20–29 years of age using a urinary theobromine to caffeine ratio [117]. However, other investigators have been unable to corroborate the validity of using caffeine as an *in vivo* probe for FMO-metabolic capacity [118,119]. Thus, it is unclear whether or not FMO3 expression levels change in elderly relative to middle-aged adults.

15.6 ALCOHOL DEHYDROGENASE (ADH)

The alcohol dehydrogenase (ADH) (EC 1.1.1.1) family of enzymes are encoded by seven genes (*ADH1A*, *1B*, *1C*, *4*, *5*, *6*, and *7*) clustered on human chromosome 4q21–q25. Functioning as dimers, the ADH enzymes catalyze the oxidation and reduction of a wide variety of alcohols and aldehydes, respectively [120]. Smith *et al.* [121] provided definitive evidence for the progressive expression of *ADH1A*, *1B*, and *1C*, during development. Using starch gel electrophoresis, ADH1 expression in liver, lung, kidney, and intestine from 222 individuals ranging in age from 9 weeks gestation to >20 years postnatal age was examined. Only *ADH1A* was detectable in 48 fetal liver samples with a mean gestational age of 13.5 weeks. By 16 weeks both *ADH1A* and *1B* were measurable, although *ADH1A* predominated and was expressed at higher levels than observed at 13.5 weeks. By 19 weeks, products from all three loci were observed, with *ADH1A* expressed at levels modestly greater than *ADH1B*, and *ADH1C* expressed at low levels in some, but not all samples. In 30 week, prematurely born infants ($n = 10$), *ADH1A* and *1B* levels were equivalent and greater than *ADH1C* while in 36-week premature infants *ADH1B* expression that dominated the other two class 1 alleles was observed. In adult liver samples, *ADH1A* expression was low to nondetectable, whereas *ADH1B* and *1C* expression were equivalent. These studies support the conclusion that birth is more important than gestational age in triggering the activation of *ADH1C* expression. In addition to the progressive change in ADH1 subfamily expression, there was an overall increase such that adult enzyme levels were 10-fold higher than those observed in first trimester fetal samples.

Similar studies in other tissues demonstrated that the observed ADH1 developmental trajectory was tissue specific [121]. No differences between the fetal and adult samples were observed in the lung and only *ADH1C* was detectable. Relative to hepatic expression, intestinal and kidney ADH1 expression was low, was dominated by expression from the *ADH1C* locus, and did not change appreciably with age during early life stages. The observations regarding hepatic ADH1 enzyme ontogeny are largely in agreement with a study in which concentrations of the different ADH1 transcripts were determined by northern blot analysis [122]. In two different fetal liver samples of unspecified age, *ADH1A*, *1B*, and *1C* transcripts were observed in one, whereas *ADH1B* and *1C* transcripts dominated in the second. Differing from the observations by Smith *et al.* [121], *ADH1A* transcripts dominated in the lung, whereas in the fetal

kidney, only ADH1B and 1C transcripts were observed. ADH1 transcripts also were present in most other adult tissues with the exception of brain, kidney, and placenta. ADH4 and ADH7 transcripts were observed in fetal liver at concentrations comparable to those seen in the adult, but only faint signals were seen in the adult small intestine and pancreas. Similar to the class I transcripts, ADH5 transcripts were widely distributed and present at approximately the same concentrations in all fetal and adult tissues examined with the possible exception of the brain. In this tissue, the ADH5 transcripts appeared higher in the fetus than in adult. Drawing conclusions from the data on transcript levels is difficult to do with confidence as the correlation between ADH protein and transcript levels in the various tissues and whether or not the degree of correlation might change as a function of age are unknowns.

Early studies evaluating alcohol first pass metabolism in middle-aged versus elderly adults, measured as the difference in serum ethanol concentrations as a function of time after oral and intravenous ethanol administration, provided controversial results regarding late life stage changes in ADH activity. Some studies demonstrated an unexpected increase in alcohol first pass metabolism in elderly versus middle-aged subjects [123], while other studies demonstrated an age-dependent effect in the opposite direction [124]. However, an *in vitro* comparison of ADH activity in either liver [125] or gastric mucosa [126] between middle-aged and elderly subjects failed to identify any impact of age using ethanol as a substrate. Using form-specific substrates, Matsumoto *et al.* [127] were able to demonstrate a small effect of age on ADH7 activity in the gastric mucosa, but not ADH1 or 5. Thus, there appear to be no or minimal changes in ADH activity in later life stages.

15.7 ALDEHYDE OXIDASE (AOX)

The two human aldehyde oxidase (AOX) (EC 1.2.3.1) family members, AOX1 and AOX2, are encoded on chromosome 2q33. These enzymes are important for the metabolism of a wide variety of aldehyde-containing and *N*-heterocyclic compounds, including 5-fluoropyrimidine, quinine, methotrexate, 6-mercaptopurine, and zonisamide, although the relative specificity of AOX1 versus AOX2 for these compounds is poorly defined. Tayama *et al.* [128] characterized AOX ontogeny in a cohort of 101 Japanese children of both sexes and ranging in age from shortly after birth to 10 years of age. The urinary AOX-dependent oxidation products of *N*1-methylnicotinamide, *N*1-methyl-2-pyridone-5-carboxamide, and *N*1-methyl-4-pyridone-3-carboxamide were evaluated as a measure of enzyme activity. Pediatric activities were compared to those observed in 26 adults, ages 20–60 years. AOX activity in neonates was only 10–15% of that observed in adults. Between 30 days and 1 year of age, activity increased in a nearly linear manner to adult levels. No correlation was observed with donor sex. Whether or not AOX activity is present in the fetus remains unknown. AOX activity was evaluated in 13 liver samples from donors ranging in age from 29 to 73 years by evaluating the kinetics of benzaldehyde and *N*-[(2-dimethylamino)ethyl] acridine-4-carboxamide oxidation to benzoic acid and the acridone, respectively [129]. Although these data were consistent with no change in AOX expression in the elderly relative to middle-aged individuals, the sample size used for this study is small and as such the results should be considered preliminary.

15.8 CARBOXYLESTERASES (CES)

There are three functional members of the human carboxylesterases (CES) gene family, *CES1-3*, located on chromosome 16q21.1–16q21.2. Although perhaps better known for their role in pesticide metabolism [130], these microsomal enzymes also are important for the hydrolysis of numerous drugs; examples include clopidogrel [131], trandolapril [132], and oseltamivir [133] predominantly by CES1 and the hydrolysis of irinotecan predominantly by CES2 [134]. Little is known regarding the substrate specificity of CES3 [135]. CES1 is expressed predominantly in the liver, whereas CES2 is the dominant enzyme in extrahepatic tissue, particularly the gastrointestinal tract [135].

Pope *et al.* [136] was the first to provide evidence for age-dependent expression of the CES enzymes in early life stages. Although limited in available tissue samples, their studies suggested lower CES activity in liver samples from a single 2-month-old donor, whereas tissue samples from 3- to 24-month-old donors exhibited activities no different than samples from 20- to 36-year-old donors. A more recent study evaluated both CES1 and CES2 transcript, protein and activity levels in selected liver samples from 104 donors ranging in age from 12 weeks gestation to >18 years [137]. Although there was considerable interindividual variability, CES1 and CES2 expression in the fetal samples was 1% or less of that observed in the adult samples. Expression of both enzymes in the 0- to 10-year old samples was ~70% of that observed in the adult. Excellent correlation of transcript and protein levels was observed for both CES1 and CES2. Although again limited by sample size within critical windows of time, a careful analysis of the data reported by Yang *et al.* [137] is consistent with mature levels of CES1 and CES2 being achieved by two to three months of age. This CES1 and CES2 developmental trajectory also is consistent with the data reported by Zhu *et al.* [138], who also demonstrated the lack of any change in hepatic CES1 or CES2 expression in tissue samples from elderly (75–85 years, $N = 8$) versus younger (12–18 years, $N = 4$) donors.

15.9 EPOXIDE HYDROLASE (EPHX)

Although several mammalian epoxide hydrolases (EPHX) (EC 3.3.2.3) exist, two are known for their important role in detoxifying often highly reactive epoxides by the addition of water to form dihydrodiols, microsomal epoxide hydrolase (EPHX1), and soluble epoxide hydrolase (EPHX2). More recently, EPHX2 also has been recognized for its critical role in the inactivation of epoxyeicosatrienoic acid signaling molecules that exhibit potent vasodilatory, anti-inflammatory, and fibrinolytic effects and as such, EPHX2 has become a therapeutic target [139].

Pacifici and Rane [140] and Pacifici *et al.* [141] were the first to demonstrate fetal EPHX1 activity in various tissues between 14 and 25 weeks gestation. Mean ($\pm$ SD, $n = 7$) styrene EPHX1 activity (nmol/min/mg protein) was reported to be 5.9 ± 1.6 in fetal liver, 3.6 ± 1.0 in adrenals, 0.6 ± 0.1 in lung, 0.5 ± 0.4 in kidney, and 0.3 ± 0.1 in intestine. In contrast, EPHX1 activity in adult liver was approximately twofold higher. Although clear differences were noted between fetal and adult liver, there was no apparent change with gestational age. By increasing the sample size to 20 and extending the age range from 10 to 25 weeks gestation, a weak correlation between gestational age and microsomal EPHX1 activity became apparent ($r^2 = 0.6$), but this relationship was

driven heavily by one or two samples [142]. EPHX1 expression differences between fetal and adult liver were corroborated by Cresteil *et al.* [143] who measured both EPHX1 protein levels and benzo[*a*]pyrene 4,5-oxide hydrolase activity in microsomal preparations from 14 fetal liver samples, ages 17–32 weeks, and nine adult liver samples. Fetal EPHX1 activities ranged from 1.0 to 3.3 nmol/min/mg protein, while adult values ranged from 6.0 to 9.7 nmol/min/mg protein and there was an excellent correlation between activity and protein concentration ($r^2 = 0.939$). None of the above studies were able to demonstrate a change in EPHX1 activity or protein levels as a function of gestational or postnatal age, although the substantial difference between fetal and adult liver samples was highly reproducible. Age-dependent changes were demonstrated by Omiecinski *et al.* [144] who determined EPHX1 catalytic activity, protein and mRNA levels in 18 fetal liver samples, ages 7.6–21.9 weeks gestation. Activity ranged from 41 pmol/min/mg protein in the 7.6 week samples to 306 pmol/min/mg protein in the older fetal samples. A high degree of correlation was observed between age and activity ($r^2 = 0.82$), as well as between protein levels and activity ($r^2 = 0.93$). Mean adult hepatic EPHX1 activity was reported as 424 ± 236 pmol/min/mg protein ($n = 15$). No correlation was observed between activity and mRNA content in either the fetal or adult samples. Finally, analysis of the data reported by Hassett *et al.* [145] on 40 liver samples from donors ranging in age from 9 to 67 years failed to identify any changes with age, consistent with the earlier conclusion by Woodhouse *et al.* [146] that EPHX1 expression does not change in the elderly relative to middle-aged individuals.

Mean EPHX2-dependent styrene oxide hydrolase activity was determined to be 0.23 ± 0.02 nmol/min/mg protein in the fetal liver, while adult values were 0.83 ± 0.05 nmol/min/mg protein [141]. Similar results were obtained with stilbene oxide as a substrate. There was no apparent change in EPHX2 activity as a function of gestational or postnatal age, despite the substantial overall differences between the fetus and adult. Similarly, there was no apparent change in EPHX2 expression in the elderly relative to middle-aged adults. However, these conclusions are based on limited sample sets and additional studies using samples from a broader age range in the fetal, perinatal, and later life stages will be needed to better address age-dependent changes in EPHX2 expression.

15.10 GLUTATHIONE S-TRANSFERASE (GST)

The glutathione *S*-transferase (GST) enzymes (EC 2.5.1.18) catalyze the nucleophilic attack of reduced glutathione toward drugs containing electrophilic carbon, nitrogen, or sulfur atoms, thereby detoxifying and often facilitating elimination. Substrates include a wide variety of halogenonitrobenzenes, arene oxides, quinones, and unsaturated carbonyls. Although there are three families of GST enzymes, microsomal, cytosolic, and mitochondrial, this chapter focuses on the cytosolic enzymes, as these are considered most important for drug metabolism [147].

The cytosolic GST enzyme family consists of 16 genes within six subfamilies: *GSTA* (α), *GSTM* (μ), *GSTO* (ω), *GSTP* (π), *GSTT* (θ), and *GSTZ* (ζ) [148]. The encoded enzymes function as dimers with members of the *GSTA* and *GSTM* families being able to form heterodimers. The GST exhibit overlapping substrate specificities, which has made it difficult to characterize individual gene expression based on catalytic activity [147].

Pacifici and Rane [140] and Pacifici *et al.* [141] demonstrated GST activity toward styrene oxide in second trimester fetal liver, adrenal, lung, kidney, and intestine that varied little among the tissues examined and ranged from 2.6 to 5.6 nmol/min/mg protein. Activity against this same substrate increased to 9.95 ± 1.75 nmol/min/mg protein in adult liver. However, members of the GSTM, GSTT, and GSTP families also exhibit activity toward this substrate making it difficult to conclude anything regarding the expression of specific proteins from these studies. The first attempt to differentiate between GST enzymes was accomplished using starch gel electrophoresis and chromatofocusing [149]. GSTM (GST1), GSTA (GST2), and GSTP (GST3) ontogeny was examined in tissue samples that were divided into five age groups: group 1, 10–20 weeks gestation; group 2, 21–30 weeks gestation; group 3, 31–42 weeks gestation; group 4, term infants who died between 2 and 67 weeks postnatal age; and group 5, adults. A progressive increase in GSTM expression was observed as a function of age. Low GSTM expression was observed in a small number of groups 1 and 2 samples accounting for 2.5–16.5% of the total GST activity. However, readily detectable protein was present in half of the group 3 tissue samples accounting for 5.0–24.5% of total activity. The postnatal samples (group 4) exhibited GSTM activities that were no different than that observed in adults, accounting for 14.9–55.3% of total GST activity. In contrast, GSTA was expressed at relatively high levels within each of the age groups, accounting for 45–90% of the total GST activity, with no apparent change with age. The GSTP developmental trajectory was the opposite of GSTM, exhibiting the highest activity in the group 1 samples (30–50% of total GST activity), declining to 10–20% of total GST activity in the group 2 samples, and was undetectable in any of the postnatal and adult liver tissue. A subsequent study by this same group [150] further refined the enzymes being examined by distinguishing between GSTA1 and A2, as well as expanding the number of study samples. GSTA1 and A2 were expressed in fetal liver and there was a significant increase of 1.5- to 2.0-fold at birth, but no change between neonatal and adult samples. In all samples, GSTA2 was present at levels ~10% of GSTA1. GSTA1 and A2 also were present in fetal lung, but at levels 0.5–1% of that observed in the liver and no increase in expression was seen at birth. GSTM and GSTP also were detectable in fetal lung at levels similar to those observed in liver, but decreased by ~50% and 30% at birth, respectively [151]. GSTA1 and GSTA2 were both expressed in fetal kidney at similar levels (0.042 ± 0.05 and 0.03 ± 0.05 $\mu\text{g}/\text{mg}$ cytosolic protein, respectively). Levels of both enzymes increased 5- to 10-fold at birth. GSTM and GSTP were present in both fetal and postnatal kidney samples at levels similar to those observed in liver [151]. Immunohistochemistry demonstrated GSTA and GSTP in both collecting tubules and developing nephrons in fetal kidney, but after 35 weeks gestation, GSTA was restricted to the proximal tubule while GSTP was restricted to the distal and collecting tubules and the loop of Henley [152]. A similar approach demonstrated widespread expression of these same enzymes, as well as GSTO in many fetal tissues [153,154]. However, the demonstration that the GST enzymes are expressed in specific cell types within lung and kidney also suggests that the earlier-measured enzyme levels from total tissue homogenates likely underestimated expression in specific cell types.

Elucidation of GSTZ1's developmental trajectory is of interest because of its critical importance in the disposition of dichloroacetate (DCA) which classically has been used to treat lactic acidosis and more recently, solid tumors [155]. Adults are at greater risk than children for DCA-induced peripheral neuropathy [156]. Evaluation of both

GSTZ1 protein and activity levels *in vitro* demonstrated very low GSTZ1 expression prenatally. Expression increased substantially in the first two weeks after birth and then continued to rise, maturing to adult levels by one year of age. There was a good correlation between protein and activity levels which was improved substantially by the segregation of the data by haplotype [157]. These data suggest that children aged greater than one year would have higher DCA clearance rates and would be less susceptible to drug-induced side effects compared to adults because of their mature levels of GSTZ1 expression combined with their greater liver mass to body surface area.

The above studies demonstrate gene-specific developmental expression patterns for selected members of the GST enzyme family. Furthermore, the relatively high levels and ubiquitous expression would suggest important roles for these enzymes during development. Yet, our knowledge currently is limited to a select few of the 16 genes that constitute the *GST* family [148], suggesting that GST ontogeny remains an important, but understudied area. Even less is known about possible changes in GST expression in the elderly, although no differences were detected in two studies evaluating GST enzyme expression in erythrocytes [158] or lymphocytes [159], but decreased expression was reported in gastric mucosa samples from the elderly [160].

15.11 SULFOTRANSFERASE (SULT)

The family of sulfotransferase (SULT) enzymes (EC 2.8.2.1) catalyze the conjugation of a sulfonate moiety donated by 3'-phosphoadenosine-5'-phosphosulfate to a wide variety of electrophilic substrates, generally resulting in inactivation and facilitated elimination from the body. The human SULT enzymes are encoded by three gene families, the *SULT1* family, associated with phenol conjugation; the *SULT2* family, associated with hydroxysteroid conjugation; and a more recently discovered *SULT4* family expressed exclusively in the brain. The *SULT1* family consists of four subfamilies encoded by seven genes (*SULT1A1*–*1A3*; *SULT1B1*, *SULT1C2* and *1C4*; and *SULT1E1*); the *SULT2* family consists of two subfamilies each encoded by a single gene (*SULT2A1* and *2B1*). The *SULT4* family consists of a single gene, *SULT4A1* [161]. No studies have been reported on the ontogeny of *SULT1A2*, *1B1*, *1C4*, *2B1*, or *4A1*. A single study evaluated the effect of increasing age in adults on paracetamol sulfation and found no impact [162].

Early studies characterized SULT ontogeny using probe substrates with the inherent problem, perhaps not appreciated at the time, of overlapping substrate specificity. Second trimester fetal liver 2-naphthol sulfotransferase activity, most likely catalyzed by one or more members of the *SULT1A* family, was reported to be 0.18 ± 0.12 nmol/min/mg, increasing approximately threefold in adults [163]. In contrast, Duanmu *et al.* [164] described the *SULT1A1* developmental trajectory by determining protein levels, quantifying western blot data by linear regression using recombinant protein as standards. Substantial expression was observed in fetal liver that was not significantly different from liver tissue donated from individuals aged 0 to 12 months or >12 months to 18 years. Stanley *et al.* [165] also demonstrated high *SULT1A1* levels in the choroid plexus using *p*-nitrophenol as a probe substrate (45 pmol/min/mg), but much less so in other regions of the brain (<5 pmol/min/mg protein). A very different expression pattern was observed in the developing lung where a progressive

decrease in SULT1A1 protein level as a function of both prenatal and postnatal age was reported along with a significant twofold decrease in expression when comparing mean prenatal to postnatal protein levels [166].

The SULT1A3 developmental trajectory has been characterized using dopamine as a probe substrate. Enzyme activity was present in a wide variety of second trimester fetal tissue with the highest level in fetal gut (200 ± 133 pmol/min/mg) followed by fetal lung and liver (122 ± 52 pmol/min/mg and 96 ± 37 pmol/min/mg, respectively) and kidney (37 ± 30 pmol/min/mg). Dopamine sulfotransferase activity was unchanged in adult gut (188 ± 33 pmol/min/mg), but was decreased in lung (78 ± 33 pmol/min/mg), liver (30 ± 15 pmol/min/mg), and kidney (11 ± 7 pmol/min/mg) [167]. Substantially greater changes were reported by Richard *et al.* [168] and Stanley *et al.* [165] with a 10-fold decrease in hepatic SULT1A3 levels between second trimester fetal (75.6 ± 52.3) and postnatal liver (6.7 ± 7.6 pmol/min/mg) and a sixfold decrease between fetal (39.7 ± 18.8 pmol/min/mg) and postnatal lung (6.6 ± 10.0 pmol/min/mg). Low SULT1A3 activity also was detected in various regions of the fetal brain (<5 pmol/min/mg protein).

Estrone and/or ethinyl estradiol have been used commonly as probe substrates for SULT1E1. Miki *et al.* [169] detected widespread SULT1E1 expression in several fetal and adult tissues, but were unable to determine any relationship with age. Expression in most fetal tissues, including relatively high levels in the fetal choroid plexus, was confirmed by Stanley *et al.* [165]. Evidence for a decrease in SULT1E1 protein levels between fetal and adult liver also was reported. Such an inverse correlation between hepatic SULT1E1 protein levels and age was confirmed by Duanmu *et al.* [164] who described a progressive decrease in fetal liver expression from the first to third trimester, a further decrease between fetal and perinatal samples, and a final decrease between perinatal samples and tissue from older children aged up to 18 years. A sexual dimorphism also was demonstrated, with males expressing higher levels than females in fetal liver tissue, which the authors speculated might protect the male fetus from excessive estrogen levels.

Although the ontogeny of SULT1C2 has not been documented, transcripts were detected in fetal kidney and liver with the greater concentration in the former tissue [170]. In a subsequent study, the highest SULT1C2 protein levels were observed in fetal small intestine, followed by fetal kidney and liver. Low protein levels were observed in a variety of other fetal tissues. Furthermore, protein levels appeared less in adult liver. No SULT1C1 was detectable in fetal brain [165].

DHEA sulfation can be used to probe for SULT2A1 enzyme levels. Barker *et al.* [171] used this reaction to demonstrate relatively low SULT2A1 activity fetal liver, but substantially increased activity in perinatal and adult samples. Furthermore, there was a good correlation between activity and protein levels. A similar trend was observed in fetal and postnatal lung, although lung SULT2A1 levels appeared to mature somewhat earlier [166]. A subsequent study by this same group documented SULT2A1 enzyme activity in fetal liver (~ 84 pmol/min/mg protein), adrenal (~ 422 pmol/min/mg protein), kidney (~ 49 pmol/min/mg protein), small bowel (~ 56 pmol/min/mg protein), and lung (~ 7 pmol/min/mg protein), but no activity in brain. A substantial increase was observed in adult liver (~ 323 pmol/min/mg protein) [165]. This SULT2A1 developmental trajectory was confirmed by Duanmu *et al.* [164] who demonstrated readily detectable protein and activity in fetal liver which increased significantly in the perinatal period and achieved adult levels in samples older than three months.

15.12 UDP GLUCURONOSYLTRANSFERASE (UGT)

The UDP glucuronosyltransferase (UGT) enzymes (EC 2.1.4.17) catalyze the conjugation of uridine 5'-diphosphoglucuronic acid with hydrophobic compounds containing functional groups, often added during oxidative drug metabolism, to form β -D-glucopyranosiduronic acids. Generally, these products are inactive and targets for facilitated renal and biliary elimination. Glucuronidation accounts for nearly 15% of drug clearance in the adult human [36]. Two human UGT gene families exist that encode 16 proteins. Nine functional genes exist in the *UGT1* family as a single locus on chromosome 2q37, *UGT1A1*, *1A3*, *1A4*, *1A5*, *1A6*, *1A7*, *1A8*, *1A9*, and *1A10*; the *UGT2* family consists of seven genes located at chromosome 4q13–4q13.2, *UGT2A1*, *UGT2B4*, *2B7*, *2B10*, *2B11*, *2B15*, and *2B17* [172]. UGT ontogeny was reviewed by de Wildt *et al.* [173] and the reader is referred to this exhaustive review for more detail. *UGT1A1*, the major enzyme responsible for bilirubin glucuronidation, is undetectable in fetal liver. Enzyme expression increases immediately after parturition in a process independent of gestational age. Adult levels of the enzyme are attained by three to six months of age. Using estrone as a probe substrate, *UGT1A3* was demonstrated in fetal and neonatal liver at levels $\sim$ 30% of those in adult tissue, but the subsequent developmental trajectory remains unknown. *UGT1A6* was present in fetal liver at 1–10% of adult levels. At birth and independent of gestational age, expression increases slowly, achieving 50% of adult values by six months of age. However, *UGT1A6* maturation is not complete until puberty.

Because of its specificity for morphine glucuronidation, several studies have been done on *UGT2B7* ontogeny. In second trimester fetal liver samples, *UGT2B7* was detectable at levels that were 10–20% of adult values. Progressive increases in expression were observed with age such that adult expression levels were attained by two to three months after birth. *UGT2B17* also was shown to be expressed in the fetal liver at levels $<$ 10% of adults. Expression increased to 10% of adult values in the neonate, but the subsequent developmental trajectory is unknown.

Strassburg *et al.* [174] conducted an exhaustive analysis of hepatic *UGT1A1*, *1A3*, *1A4*, *1A5*, *1A6*, *1A8*, *1A9*, *1A10*, *2B4*, *2B7*, *2B10*, and *2B15* ontogeny in 16 infant liver samples, ages 6–24 months, comparing these data to that obtained from 12 adult patients. In addition, RNA from two second trimester fetal samples was available. No UGT transcripts were detected in the two 20-week gestation fetal samples. Although these data conflict with earlier reports wherein low levels of UGT activity and/or protein level were detected, all of the available data are consistent with the onset of low UGT activity during the latter half of the second trimester or the third trimester. Transcript levels in the infant samples were binned into three age brackets, 6–12 months, 13–18 months, and 19–24 months, and compared among themselves and to adult levels. No difference was observed between any of these age brackets and adult *UGT1A1* or *UGT2B7* transcript levels. In contrast, there was a progressive increase in *UGT1A9* transcripts as a function of age. For *UGT2B4*, there were no differences among the different pediatric age groups, which all exhibited protein levels 30–40% of those in adults. The catalytic activities within all of the pediatric age groups were lower than that observed in the adult samples. These data are consistent with a report by Zaya *et al.* [13] who described the maturation of *UGT2B7*-dependent epirubicin glucuronidation. A progressive increase in *UGT2B7* activity was observed across five age groups, $<$ 1 year, 1–5 years, 6–11 years, 12–17 years, and adult. However, allometric scaling

using the 3/4 power rule [175] predicted that UGT2B7-dependent clearance would be attained by two to three months of age, consistent with *in vivo* studies. The more recent study by Miyagi and Collier [176] also is consistent, providing evidence for the maturation of overall hepatic to adult levels by 20 months and more specifically, the maturation of hepatic UGT1A4 activity by 17 months of age.

Studies performed to date would suggest no change in UGT activity in the elderly. Thus, for a variety of benzodiazepines cleared primarily by glucuronidation, there were no or minimal decreases in clearance in older patients [177,178]. Similarly, no differences in paracetamol glucuronidation were observed in patients ranging in age from 40 to near 90 years [162]. Most recently, the glucuronidation of valproate by UGT1A4, 1A8, and 1A10 was evaluated in a bank of liver microsomes from young (2–56 years of age) and elderly (>65 years of age) donors and no differences were observed [179].

15.13 CONCLUSIONS AND FUTURE PERSPECTIVES

Evaluating what is currently known regarding the developmental trajectories of the human hepatic DMEs reveals a pattern consistent with the binning of the enzymes into one of three classes depending on the individual temporal-specific expression patterns (Table 15.1). Class I enzymes are expressed at relatively high levels during the first trimester. The expression of these enzymes either remains elevated or decreases during gestation. However, within a few days to as long as two years after birth, expression is either silenced or reduced to low levels. An obvious question is whether or not class I enzymes have an important endogenous function during hepatic development. Enzymes belonging to class II are expressed at relatively constant levels throughout gestation and into adulthood. Expression may or may not increase modestly within the first year after birth. Finally, class III enzymes are not detectable or are detected at low levels in the fetus. For some, the onset of expression can be seen in either the second or third trimester, but levels remain substantially less than those observed in the adult. Significant increases in expression are observed within the first one to two years after birth; however, full maturation does not occur until postpuberty for a few of the class III enzymes. Class III also appears to include the largest number of enzymes. The developmental trajectories for human hepatic FMO1, CYP2C19, and

TABLE 15.1 Classification of Drug-Metabolizing Enzymes Based on Developmental Trajectories

Class I	Class II	Class III	
ADH1A	CYP2B6	ADH1B	GSTM
CYP1A1	CYP2C19	ADH1C	GSTZ
CYP3A7	CYP3A5	AOX	FMO3
FMO1	EPHX1	CYP1A2	PON1
GSTP	EPHX2	CYP2A6	SULT2A1
SULT1E1	GSTA	CYP2C8	UGT1A1
SULT1A3	SULT1A1	CYP2C9	UGT1A6
		CYP2D6	UGT2B7
		CYP2E1	CES1
		CYP3A4	CES2

Figure 15.1 Developmental trajectories of class I, class II, and class III enzymes. Human FMO1 (hatched bars), CYP2C19 (white bars), and CYP2C9 (gray bars) hepatic protein expression levels as a function of age are depicted to illustrate the developmental trajectories typical of class I, class II, and class III enzymes, respectively. Data are plotted as medians (bars), interquartile values (boxes), and tenth to ninetieth percentiles (whiskers). Outliers were defined as 1.5 times the interquartile values. *Source:* Data on the expression of FMO1 in pediatric samples was derived from Koukouritaki *et al.* [112]. Data on the expression of CYP2C9 and CYP2C19 in pediatric samples was derived from Koukouritaki *et al.* [51]. Data on the expression of CYP2C9 and CYP2C19 in the adult were derived from Lapple *et al.* [180].

CYP2C9 as examples of class I, class II, and class III enzymes, respectively, are shown in Fig. 15.1. Whether or not this classification of enzymes also will apply to developmental trajectories in extrahepatic tissues remains to be seen.

For those DME that belong to class III, most if not all exhibit greater interindividual variability during the perinatal period compared to other age brackets. This observation is most apparent in scatter plots of the developmental expression data presented in some of the original reports on FMO3 [112], CYP2C9 [51], CYP2E1 [82], and CYP3A4 [94]. This is largely explained by what appears to be interindividual variability in the timing of the postnatal increase or onset of expression of these enzymes. As an example, both CYP2C9 and 2E1 exhibited an ~ 100 -fold range of expression in the perinatal period, which was approximately two times greater than that observed within any other age bracket. Thus, there would appear to be windows of hypervariability during drug-metabolizing enzyme ontogeny that would significantly impact risk for adverse drug reactions and/or failed efficacy and would not be predicted based on adult pharmacogenetic studies.

For multiple enzyme families with members belonging to both class I and class III, the term *developmental switch* is often used to describe the transition between the predominant fetal to the predominant adult enzyme form. However, in none of these enzyme systems is there any evidence for coordinated inverse regulation between these

“fetal” and “adult” enzymes, suggesting the term *developmental switch* is a misnomer and that developmental transition is a more appropriate description of this process. Consideration of these data also suggests that for enzyme systems such as CYP2C9 and 2C19 that appear to share some regulatory mechanisms in the adult, mechanisms regulating ontogeny are strikingly different.

Although improving, there remains a need for additional studies to define the true ontogeny of many of the enzyme systems, particularly in extrahepatic tissues. Too much of our current knowledge is based on data from tissue samples or *in vivo* studies that utilized samples or recruited patients representing narrow time windows. Conclusions drawn from such studies can be contradictory and misleading. Despite these knowledge gaps, the knowledge base is sufficiently robust to support the development of physiologically based pharmacokinetic models that provide a much improved means of predicting age-specific drug disposition [181–184]. Further advances in the field will only improve these valuable tools.

16.1 SUMMARY

Plant secondary metabolites (PSMs) have been components of man’s diet for millennia and are believed to have played a significant role in steering the functional development of xenobiotic metabolizing enzymes (XMEs) and transporters within the human gastrointestinal tract. Only recently, however, PSMs have been recognized

as modulators of human drug disposition. Despite exposure to thousands of structurally diverse dietary phytochemicals, only a few appear to significantly modulate human drug-metabolizing enzymes and transporters. In some instances, these interactions may have beneficial effects, such as cancer prevention (i.e., isothiocyanates in cruciferous vegetables), whereas others may dramatically affect the pharmacokinetics of concomitantly administered drugs (i.e., furanocoumarins in grapefruit juice). In today's global economy, the opportunity for exposure to more exotic phytochemicals is significantly enhanced. Formulated as concentrated phytochemical extracts, botanical dietary supplements are vehicles for a host of PSMs rarely encountered in the normal diet. When taken with conventional medications, botanical dietary supplements may give rise to clinically significant herb–drug interactions. These interactions stem from phytochemical-mediated induction and/or inhibition of human drug-metabolizing enzymes and transporters.

In this chapter, the herb–drug interaction risks and mechanisms for several of the most popular dietary supplements are discussed. Botanicals most likely to produce clinically important herb–drug interactions are those whose phytochemicals act as mechanism-based inhibitors of cytochrome P450 enzyme (CYP) activity (e.g., *Hydrastis canadensis*, *Piper nigrum*, and *Schisandra chinensis*) or function as ligands for orphan nuclear receptors (e.g., *Hypericum perforatum*). In addition, several external factors unrelated to phytochemical pharmacology can augment the drug interaction potential of botanical supplements.

16.2 INTRODUCTION

Since the dawn of man, plants have been a rich source of food and medicine. Thus, an almost constant exposure to an enormous array of plant-derived chemicals (phytochemicals) has had a profound influence on human evolutionary and social development. Unbeknownst to many, evolutionarily ancient phytochemicals lie at the root of man's ability to metabolize modern-day drugs. This is because as humans we have, in a sense, phylogenetically “inherited” the multiplicity of XMEs and transporters necessary for detoxifying dietary and environmental chemicals. In effect, the expression and activity of human XMEs and transporters have been shaped by man's exposure to phytochemicals, either as dietary components or as natural medicines.

Modern drugs, many of which are derived from plant sources, are pharmacologically potent single-chemical entities, and XMEs and transporters are important determinants of their absorption, metabolism, distribution, and excretion. A variety of exogenous factors (e.g., diet, drugs, and environmental chemicals) can modulate XME and transporter activity. These factors, in turn, can affect the efficacy and toxicity of concomitantly administered medications. While most health care professionals and many laypersons are familiar with the concept of drug–drug interactions, as well as their adverse consequences, few recognize that many fruits and vegetables can also interact with conventional medications. Moreover, the recent upsurge of herbal dietary supplement usage and the influx of non-Western medical practices (e.g., traditional Chinese medicine (TCM), ayurvedic medicine, and Kampo medicine), that frequently incorporate a variety of botanical extracts, pose additional concerns. Together, fruits, vegetables, and especially botanical dietary supplements form the basis for this newly recognized category of herb–drug interactions.

Herb–drug interactions, while ancient in their origins, can have devastating consequences in today’s culturally diverse health care environment. In the last decade, several clinically significant herb–drug interactions have been recognized, prompting a surge of research into their cause and mechanism. Essentially two types of herb–drug interactions can be ascribed: pharmacodynamic and pharmacokinetic. Pharmacodynamic herb–drug interactions involve botanicals and conventional medications that enhance or negate each other’s effects as a result of similar or disparate pharmacologic activity, respectively. For example, weight-loss supplements formulated with *Ephedra sinica* can negate the effects of many antihypertensive medications due to the sympathomimetic effects of ephedrine alkaloids. Pharmacokinetic herb–drug interactions arise from the ability of phytochemicals to modulate the activity of XMEs and/or various drug transporters involved in the disposition of conventional drugs. This chapter focuses on pharmacokinetic herb–drug interactions, with an emphasis on their sources, causes, and clinical relevancy.

16.3 PLANT–ANIMAL “WARFARE” AND THE EVOLUTION OF METABOLIC DEFENSE MECHANISMS

Phylogenetic analyses indicate that the evolution of vertebrate XMEs, transporters, and their nuclear receptor regulators began 400 million years ago in a “war” of sorts between terrestrial plants and animals [1–5]. According to the hypothesis, as insects and higher order animals began feeding on plants; the plants, in turn, synthesized toxic phytochemicals as a means of deterring herbivory. Because plants are sessile autotrophs (organisms that synthesize organic compounds from inorganic sources of carbon and energy) incapable of avoiding predation by heterotrophs (organisms that use organic carbon for growth by consuming other organisms), they have invested heavily into chemistry for their survival. One of the principal returns on this investment is the ability to synthesize a myriad of phytochemicals known as *PSMs*. Although not part of the primary biochemical pathways of cell growth and reproduction, PSMs are involved in regulation of symbiosis, defense against herbivores and pathogens, and chemical inhibition of competing plant species [6,7]. As plants evolved and adapted to more difficult environmental stresses, so did the variety, complexity, and toxicity of their resident PSMs. These defense phytochemicals influence herbivores and microbes in a negative manner by interfering with one, or oftentimes several, molecular targets (e.g., receptors, enzymes, and other proteins). The structures of defense phytochemicals appear to have been shaped during evolution in such a way as to mimic the structures of endogenous substrates, hormones, neurotransmitters, or other ligands found in animals—a process termed *evolutionary molecular modeling* [8].

With the ingestion of myriad nonnutrient PSMs over millions of years, mammalian detoxification systems coevolved into an intricate system of XMEs, transporters, and nuclear receptors familiar to most biologists and pharmacologists today. In the case of mammals, detoxification of PSMs is accomplished through combinations of intestinal and hepatic XME-mediated oxidative, reductive, and hydrolytic biotransformations (phase I metabolism); conjugation reactions (phase II metabolism); or transporter-mediated efflux into the gut lumen or bile (phase III). Over time, continued exposure to multitudes of structurally diverse PSMs appears to have shaped the specificity, capacity, and the “promiscuity” of mammalian transporters and XMEs, rendering them

effective at recognizing, transforming, and excreting a multiplicity of xenobiotic structures. This constitutes a mammalian catabolic antidote to plant biosynthetic chemical warfare [1–5].

16.4 PLANT SECONDARY METABOLITES (PSM): PLANT SYNTHESIS VERSUS HUMAN METABOLISM

PSMs number in the tens of thousands and include such structurally diverse groups of organic compounds such as polyphenolics, alkaloids, nonprotein amino acids, polyketides, terpenes, steroid and triterpenoid saponins, cyanogenic glycosides, glucosinolates, flavonoids, phenylpropanoids, and others [6,7,9]. Central to PSM biosynthesis and accumulation are a host of plant enzymes and membrane transporters, including several whose homologous mammalian forms are familiar to most life scientists: CYPs, uridine diphosphate glycosyltransferases (UGTs), glutathione *S*-transferases (GSTs), sulfotransferases (SULTs), ATP-binding cassette transporters (ABC transporters), and solute carrier membrane transport proteins (SLCs).

CYPs, a group of heme-containing metalloenzymes, catalyze a host of crucial biological oxidation reactions in both prokaryotes and eukaryotes. In most cases, these reactions can be summarized as activation of the substrate to a reactive intermediate using electrons from nicotinamide adenine dinucleotide phosphate (NADPH) through the action of NADPH-reductase, followed by the introduction of an oxygen atom to form a more polar product. In plants, CYPs are ubiquitous. Fifty-nine families have been identified and most of them play an integral role in the synthesis of endogenous PSMs by catalyzing a wide variety of monooxygenation/hydroxylation reactions [10]. Plant CYPs also mediate the oxidative biotransformation of xenobiotics such as herbicides/pesticides into more polar, less phytotoxic compounds (phase I metabolism).

A host of UGTs, GSTs, and SULTs, catalyze the transfer of polar functional groups—sugars, sulfate, and sulfhydryl, respectively—to a wide variety of substrates as a means of increasing hydrophilicity. These polar moieties improve PSM water solubility and transportability. Of the 19 families of plant UGTs, all transfer nucleotide-diphosphate-activated sugars to low molecular weight aglycone substrates thereby increasing their water solubility and providing access to active membrane transport systems that recognize glucosides but not aglycones [11–13]. SULTs and GSTs participate in several synthetic pathways; however, the extent of their involvement in PSM production has yet to be fully elucidated [14,15]. Recently, considerable attention has been paid to plant transferases and their role in propagating resistance to man-made agrochemicals [16]. Resistance develops when plants upregulate both CYPs and transferases in response to continued herbicide exposure [17]. As phase II catalysts, UGTs, GSTs, and SULTs conjugate and further detoxify metabolites of herbicides and pollutants. These conjugated xenobiotics, in turn, are readily sequestered into plant vacuoles, where their phytotoxic threat is significantly diminished [16,17].

The ABC transporter proteins are a large and diverse superfamily of mainly membrane-bound proteins ubiquitous in all organisms, the hallmark of which is their ability to derive energy from ATP hydrolysis to actively transport molecules through membranes against a concentration gradient. Plants are a rich source of ABC transporters. More than 130 ABC protein genes have been identified in the genomes

of both monocot (*Oryza sativa*) and dicot (*Arabidopsis thaliana*) plants [18]. Among their various functions is the transport of PSMs within and between cells and cellular organelles [18]. Plants utilize ABC transporters to concentrate PSMs in those tissues vulnerable to herbivory, infection, or other stresses [18,19]. Unlike mammals, plants cannot excrete xenobiotic metabolites; therefore, ABC proteins aid in the transport of glycosylated metabolites (a phase III process) into vacuoles and the cell wall, where they are sequestered and their phytotoxicity is neutralized.

Solute carrier proteins (SLCs) promote the transmembrane movement of molecules without the hydrolysis of ATP. They can function as uniporters if a single type of molecule is transported down an electrochemical gradient, symporters if two molecules are moved simultaneously in the same direction, or antiporters if two molecules are exchanged in opposite direction. Although several SLC families (e.g., SLC7, SLC13, SLC17, SLC22, SLC36, and SLC38) have been identified as transporters of positively and negatively charged endogenous substrates essential to primary metabolism (e.g., monovalent and divalent cations, amino acids) [20], their role in the transport of PSMs remains largely unknown. Since most members of the SLC22 family in bacteria and animals are polyspecific (i.e., carry multiple substrates) and transport both endogenous and exogenous compounds including many plant-derived drugs; it is likely that several plant SLC22 members also function in the transport of charged PSMs [21]. Taken together, CYPs, UGTs, GSTs, SULTs, as well as ABCs, and perhaps SLC proteins, comprise an important assemblage of enzymes and transporters vital to the synthesis and accumulation of secondary metabolites in plants.

In order to detoxify noxious PSMs, vertebrate animals developed analogous enzymes and transporters within their gastrointestinal tracts, in addition to several heterologous transporters not found in plants [e.g., organic anion transporting polypeptides (OATPs, SLC21s)]. Unlike plants, which utilize CYPs, UGTs, and ABC transporters primarily for PSM synthesis and storage, mammals use them to metabolize and eliminate PSMs.

Of the 18 identified CYP families in humans (41 fewer than in plants), only 3 (CYP1, 2, 3) are involved in the catalytic oxidation of xenobiotics, including PSMs [22]. Within these families, nine specific isoforms constitute the bulk of human phase I reactions: CYP1A2, CYP2A6, CYP2B6, CYP2C8, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4/5. Of these, CYP3A4/5 is perhaps the most important, as it is involved in metabolizing almost half of all conventional medications. CYP2D6 and CYP2C9 rank second and third, respectively in numbers of drugs affected. These enzymes catalyze a variety of reactions including hydroxylations; dehalogenations; deaminations; N-, S-, and O-dealkylations; epoxidations; N-oxidations; peroxidations; and sulfoxidations, which usually render molecules more polar and easier to excrete. Present at high concentrations in intestinal enterocytes and liver hepatocytes, CYPs are the principal mediators of human phase I metabolism [22].

As for human UGTs, just 10 specific enzymes from 2 families (UGT1A and 2B) catalyze the bulk of all xenobiotic conjugations [23]. Like CYPs, UGTs are found in high concentrations in the intestine and liver. Unlike their plant homologs, however, human UGTs utilize glucuronic acid as the donor sugar. Glucuronide conjugates are more water soluble and, in many cases, less bioactive. Five classes of human GSTs catalyze the nucleophilic attack of glutathione on electrophilic substrates, which in the case of lipophilic PSMs, enhances their solubility and elimination [24]. Two families of SULTs, SULT1 and 2, which comprise 10 separate isoforms, carry out the transfer of a sulfate group to dietary PSMs [25]. As with most conjugation reactions, sulfonation usually

renders a substrate less toxic. SULTs, however, may activate certain PSMs that are pro-carcinogens (e.g., estragole and safrole) [26]. Collectively, the conjugative capabilities of UGTs, GSTs, and SULTs constitute the bulk of human phase II metabolism.

Approximately 50 ABC transporters have been discovered so far in humans, 14 of which are related to the efflux of xenobiotics from various cell types [27,28]. ABCs are expressed in a variety of tissues, often in normal epithelial cells such as the brush border membrane of intestinal enterocytes, the canalicular surface of hepatocytes, and the apical membrane of proximal renal tubular cells [27,29]. ABCs, in these tissues, are believed to play protective roles; intestinal ABCs limit the absorption of xenobiotics, whereas liver and kidney ABCs facilitate elimination of xenobiotics through biliary and urinary excretion, respectively [30]. Among the most studied ABC transporters is ABCB1, also known as *P-glycoprotein* (*P-gp*) or multidrug resistance protein 1 (MDR1). Highly expressed in the intestine, liver, and brain, ABCB1 functions as an efflux pump exhibiting broad substrate specificity, including affinity for many PSMs [27–30]. It is now well recognized that the phase III safeguard provided by ABCs works in concert with phase I and II enzymes to restrict systemic PSM exposure.

Two solute carrier families (SLC21 and SLC22) function in humans as uptake transporters for a variety of endogenous and exogenous anions, cations, and zwitterions [27]. Specific members of these families may be found on the apical and/or basolateral surfaces of cell membranes in a host of tissues [27,30]. It is as substrates for these polyspecific SLCs that many PSMs gain access to intestinal enterocytes and hepatocytes, at which point they can be acted on by XMEs and ABC transporters.

As a general rule, human XMEs and transporters exhibit broad substrate specificity, a characteristic that may be an adaptation to the selective pressures of an evolutionarily long and varied exposure to dietary PSMs [31]. In contrast, plant CYPs display much narrower substrate specificities [17,32]. Such differences underscore the discrete roles these proteins play in plants, where they function in PSM synthesis and accumulation, versus humans, where their purpose is to metabolize and excrete PSMs. At first glance, this impressive collection of plant and animal proteins appears to be working at cross-purposes, yet they actually share a common goal of defense of the organism.

16.4.1 PSM-Mediated Modulation of Human Drug Disposition

When consumed as part of the normal diet or as constituents in dietary supplements, many PSMs have the ability to modulate (inhibit or induce) the activity of human XMEs and transporters [33,34]. For most transporters, transferases, and CYPs, PSM-mediated inhibition at the protein level can be broadly classified as competitive or noncompetitive. Competitive inhibition occurs when PSMs simply compete with another substrate (e.g., drug) for either a transporter's binding domain or an enzyme's catalytic pocket, whereas noncompetitive inhibition involves binding at a position other than the active site (i.e., an allosteric site). In both competitive and noncompetitive inhibition, the effects are reversible. PSMs may, however, also produce irreversible inhibitory effects, to which CYPs are particularly susceptible [33]. This process, known as *mechanism-based inhibition*, involves catalytic activation of the PSM to produce a reactive metabolite (i.e., metabolic intermediate or MI) that irreversibly binds to and inactivates the CYP. Compared with reversible inhibition, mechanism-based inhibition of CYPs by PSMs more frequently cause clinically important herb–drug interactions, as the inactivated enzyme has to be replaced by newly synthesized CYP protein [33].

Induction of XMEs and transporters by PSMs generally occurs via ligand-activated transcription factors [35]. Distributed in the liver, intestine, and other tissues, these cytosolic proteins, or nuclear receptors, can sense a wide variety of xenobiotics and act as master regulators of XME and transporter expression [36]. Ligand-bound nuclear receptors form heterodimers with related coactivator proteins and translocate to the cell nucleus. There, these protein complexes bind several distinct DNA elements of XME and transporter genes to activate their transcription. Among the human nuclear receptors that recognize PSMs are the aryl hydrocarbon receptor (AhR), a regulator of CYP1A2 and ABCB1; the pregnane xenobiotic receptor (PXR), a promiscuous xenosensing regulator of CYP2A, CYP2B, CYP2C, CYP3A, UGT1A, SULT2A, GSTs, various ABC transporters; and the constitutive androstane receptor (CAR), which directs the expression of CYP2B6, CYP2C9, CYP3A4, UGT1A, SULT2A, GSTs, and certain ABC isoforms. Considerable cross talk also occurs among the nuclear receptors, as they can share ligands, DNA-binding elements, and coactivators [37]. Simultaneously with CYP and ABC upregulation, ligand-bound nuclear receptors may decrease SLC expression, a response in line with their function as xenosensors [27,37]. In short, these regulatory processes ensure optimized XME and transporter expression in the milieu of PSM exposure. Of the many XMEs and transporters under the control of nuclear receptors, CYP2E1 is an exception. Induction of CYP2E1 occurs posttranscriptionally, presumably by stabilization of enzyme degradation [38].

The heterogeneous nature of PSMs and their effects on human XME and transporter activity is exemplified by the sulfur-containing glucosinolates found in cruciferous vegetables. When ingested in sufficient quantities, vegetable glucosinolates are converted to isothiocyanates, which can inhibit certain CYP isoforms (e.g., CYP1A2 and CYP2E1) while inducing the activity of various GSTs and UGTs [39]. Other noteworthy examples include hyperforin, a prenylated phloroglucinol found in St. John's wort (SJW) (*Hypericum perforatum*), and isoquinoline alkaloids present in goldenseal (*Hydrastis canadensis*) [33]. Hyperforin, a potent PXR ligand, induces several CYPs, UGTs, and ABC transporters; while the isoquinoline alkaloids berberine and hydrastine are mechanism-based inhibitors of CYP3A4 and CYP2D6. From an evolutionary viewpoint, it is understandable why XME and ABC transporter induction can be beneficial to mammals, as this mechanism would facilitate elimination of potentially harmful dietary PSMs. From the plant's perspective, an ability to metabolically activate PSMs into more toxic species by stimulating XME expression in animals may be just one course of action in a multiple defense strategy. Many dietary PSMs, for example, are procarcinogens that require either CYP- (e.g., sinigrin, an allyl isothiocyanate found in brown mustard) or SULT-mediated activation (e.g., safrole and estragole) [40]. Granted, PSM-induced carcinogenesis is an unlikely mechanism for deterring herbivory, as cancer usually affects animals after the reproductive stage. These activated chemicals also would not have a detrimental effect on a population nor would they play a role in evolutionary selection over time [41]. Nevertheless, a means for generating toxic PSMs through bioactivation could be a beneficial adaptation for the plant.

Inhibiting animal XMEs may be another favorable defense tactic for plants, especially if the absorption of one group of PSMs is facilitated through competitive or noncompetitive inhibition mechanisms produced by a second group. A multitude of unique PSMs can be present in a given plant species and, when consumed, these selected chemical entities may work in concert through XME or ABC transporter inhibition—and possibly induction—to promote the exposure of one PSM at the

expense of another. An example familiar to most pharmacologists is the mechanism-based inhibition of human intestinal CYP3A4 by furanocoumarins present in Rutacea spp. (e.g., grapefruit, and Seville orange) [42]. When concomitantly ingested, the citrus furanocoumarins bergamottin and 6',7'-dihydroxybergamottin can significantly increase the oral bioavailability of various CYP3A4 drug substrates [43]. However, it remains to be determined if the absorption of other grapefruit PSMs are similarly affected by the inhibitory effects of furanocoumarins. In itself, grapefruit juice is not harmful to humans, but its ability to inhibit CYP3A may have evolved as a successful defense ploy against other species.

Of course, PSMs generated by plants in response to stresses imposed by one species may actually prove beneficial when ingested by another species. Fruits and vegetables as part of the human diet are a case in point. Owing to the variety of fruits and vegetables consumed by humans, PSM-mediated inhibition of XMEs and transporters may have salutary effects. For example, CYP2E1 catalyzes the activation of certain nitrosamines and other environmental carcinogens [44,45]. Inhibition of CYP2E1 activity and expression by organosulfur compounds present in garlic was correlated with a reduced tumor incidence in rat models of carcinogenesis involving nitrosamines [46,47]. Moreover, allyl sulfides in garlic oil and isothiocyanates from watercress have been shown to selectively inhibit human CYP2E1 *in vivo* [48,49]. While not conclusive, such effects likely represent one of many mechanisms to explain why diets rich in sulfur-containing PSMs appear to be chemopreventative [39,50]. Similar effects are likely related to interactions between PSMs and other XMEs and transporters.

The aforementioned examples illustrate that defensive strategies devised by both plants and animals, as a result of their continued "warfare," have garnered biological defeats and victories for both sides. From the human perspective, the savage nature of certain battles in this "war" is still visible within the genetic code.

16.4.2 Dietary PSMs and Human CYP Polymorphisms

For thousands of years, plants have been an integral component of the human diet and, as a result, man has developed an efficient means for detoxifying plant-derived xenobiotics. Several lines of evidence, however, point to man's continued exposure to unique phytochemicals, or lack thereof, as a possible mechanism for establishing genetic polymorphisms in XMEs [31,41,51]. Allelic variants in CYPs found among various ethnic groups are believed attributable, at least in part, to diets enriched by plants indigenous to specific geographic regions of the world [51]. Support for this hypothesis is coupled to the historical use of nitrogenous plant alkaloids among peoples of North Africa and the Middle East and the prevalence of the CYP2D6 ultrarapid metabolizer (UM) phenotype in these populations [52].

CYP2D6 is an important human CYP isoform with regard to xenobiotic metabolism in that it catalyzes the metabolism of many nitrogen-containing drugs and has a high affinity for plant alkaloids [52,53]. Two other characteristics are also notable for CYP2D6: the enzyme is polymorphic, and it is not inducible [52]. Allelic variants of the *CYP2D6* gene yield a range of xenobiotic metabolizing phenotypes: *poor metabolizer* (i.e., homozygous for inactive alleles), *intermediate metabolizer* (heterozygous for an active and inactive allele), *extensive metabolizer* (homozygous for active alleles), and *UM* (multiple copies of active alleles). Generally, most polymorphisms in CYP genes are of low frequency, but several are found with relatively high frequency in certain

populations. For example, the incidence of the CYP2D6 UM phenotype is ~10%, 20%, and 30% for people originating from Turkey, Saudi Arabia, and Ethiopia, respectively, whereas UMs are uncommon in Northern Europe (1–2%) and virtually absent in Asia [52,54]. This polymorphism occurs at rates far higher than can be accounted for by random mutation events and is believed to reflect selection pressures resulting from early exposure to local edible and medicinal plants [51,54,55]. Perhaps not coincidentally, North Africa and the Middle East are host to many plants whose nitrogenous alkaloids are CYP2D6 substrates. The opium poppy, a source of nitrogen-containing opioids, is native to the Turkish region, and khat (a plant containing amphetaminelike compounds) is native to Northeast Africa and is ubiquitously chewed in Ethiopia and the Arabian Peninsula [55].

That CYP2D6 is not inducible may have rendered it more susceptible to dietary pressures that select for expression of multiple copies of functional alleles. This adaptation would have allowed subjects to more efficiently detoxify plant toxins. It has been proposed that this selection pressure occurred in Northeast Africa ~5000–10,000 years ago during periods of starvation, which favored survival of those subjects exhibiting the UM phenotype [54,56]. Such a selection would have increased the number of plants available to provide useful food. Subsequent migrations to the Mediterranean area may also explain the high frequency of UMs in Southern Europe [52,56].

The reasons for mutant CYPs, which gave rise to slow-metabolizer phenotypes, are not known, but it is possible that during the course of human evolution the requirement for detoxification of nitrogenous plant alkaloids became unnecessary because of dietary changes. Thus, allelic variants, which would have spontaneously arisen, may have become established in the human genome due to lack of coevolutionary pressures to suppress them [31]. In other words, elimination of dietary pressures that had selected for functional XMEs now favored selection of polymorphs with reduced function. Similar arguments have been made to explain the frequency of CYP2A6 reduced function alleles among Japanese [55], the slow-acetylator phenotype for *N*-acetyltransferase among Caucasians [51], and the ethnic distribution of glucose-6-phosphate dehydrogenase mutations [51]. One prominent researcher in the field provided a succinct summation of the theory: “It is very likely . . . that 6000 years of a diet principally of goat meat and milk products—compared with that principally of tropical fruits and plants—might lead to XME polymorphisms” [51].

Over the last 10,000 years, the advent of agricultural practices and plant domestication has, in many instances, reduced the number and type of toxic PSMs commonly encountered in the human diet, and increased the content of beneficial phytochemicals [57]. This circumstance has become even more pronounced in the last 100 years with the global distribution of domesticated grains, fruits, and other plant foodstuffs, in effect leavening man’s exposure to more common PSMs. Today, many PSMs present in fruits and vegetables (e.g., flavonoids and polyphenolics) are thought to possess beneficial health effects, especially with regard to the prevention of chronic diseases (e.g., cancer, cardiovascular disease, and diabetes) [58–63]. As mentioned previously, modulation of XMEs and transporters are among the various pharmacologic mechanisms underlying the salutary effects of fruit and vegetable consumption. Yet, when taken concurrently with conventional medications, these mechanisms may give rise to clinically important drug interactions. Although this chapter focuses on botanical dietary supplements and their potential to effect clinically

important herb–drug interactions, two examples that involve foods—cruciferous vegetables and citrus juices—merit discussion.

16.5 FOOD–DRUG INTERACTIONS: CRUCIFEROUS VEGETABLES AND CITRUS JUICES

That food can affect drug disposition has been recognized in the pharmacy profession for decades [64–67]. The effect of meals and their composition (i.e., protein, carbohydrate, lipid) on the rate and extent of drug absorption remains an area of active research [68–71], with several new emerging theories on the role of dietary lipids in enhancing bioavailability [72,73]. Only recently, however, has an appreciation developed for the ability of dietary phytochemicals to alter drug absorption and disposition. Of the myriad foods present in the modern diet, cruciferous vegetables and citrus juices provide two classic illustrations of how common dietary phytochemicals may underlie clinically important food–drug interactions.

16.5.1 Cruciferous Vegetables

Cruciferous crops belong to the family Brassicaceae (also known as *Cruciferae*) and include such vegetables from the genus *Brassica* as broccoli (*Brassica oleracea* var. *italica*), brussels sprouts (*B. oleracea* var. *gemmifera*), cabbage (*B. oleracea* var. *capitata*), cauliflower (*B. oleracea* var. *botrytis*), mustards (*Brassica juncea*), turnips (*Brassica rapa* var. *rapa*), as well as watercress (*Nasturtium officinale*), radish (*Raphanus sativus*), and others. Unique to dietary crucifers are the glucosinolates, a group of sulfur-containing PSMs whose hydrolyzed metabolites appear to have cancer preventative properties. Synthesized by various plant CYPs, the glucosinolate molecule consists of a β -thioglucose unit, a sulphonated oxime unit, and a variable side chain derived from an amino acid. (Fig. 16.1) [74]. When cut or chewed, cruciferous vegetables release myrosinase, an enzyme that catalyzes the hydrolysis of glucosinolates to form isothiocyanates, epithionitriles, or thiocyanates (Fig. 16.1). Cooking (mild or prolonged) may inactivate myrosinase affecting the type and content of hydrolytic metabolites formed. As a result of cooking, those glucosinolates that escape myrosinase hydrolysis may still be converted to isothiocyanates in the gut via microbial activity, although the bioavailable content is much reduced [39,74].

The chemopreventative effects of cruciferous vegetables and their associated PSMs have been widely studied in a variety of experimental models [75]. To date, the preponderance of these studies have focused on isothiocyanates, which are believed to protect against the carcinogenicity of various environmental chemicals (e.g., nitrosamines, heterocyclic amines, and polyaromatic hydrocarbons). In animal models, isothiocyanates appear to inhibit CYP1A2, CYP2E1, and CYP3A4, while the activities of various GSTs, UGTs, and SULTs are induced [50,75]. This combination of CYP inhibition and transferase induction is believed to account, in part, for the chemoprotection offered by cruciferous vegetables [39].

Clinical studies employing cruciferous vegetable diets, while providing less-compelling proof of chemoprevention, have also demonstrated differential modulatory effects on human XMEs and transferases. More than 30 years ago, diets supplemented with brussels sprouts (150 g, twice daily) and cabbage (100 g, twice daily) were found

to increase the clearance and reduce plasma concentrations of the nonspecific phase I probe, antipyrine [76], as well as the drug acetaminophen [77]. For acetaminophen, the diets significantly enhanced glucuronide metabolite formation [77]. Soon after, watercress (50 g, once daily) was shown to decrease plasma concentrations of CYP2E1-generated acetaminophen metabolites [78], while the AUC of chlorzoxazone, a recognized CYP2E1 substrate [49], was markedly increased. Watercress also increased glucuronidation of a nicotine metabolite [79], but seemed to have little effect on nicotine oxidation, a marker of CYP2A6 activity. Surprisingly, broccoli (500 g/day for 12 days) had no effect on chlorzoxazone metabolism, but appeared to increase the caffeine/paraxanthine metabolic ratio, an indicator of CYP1A2 activity [80]. Such observations appeared to correlate with *in vitro* CYP-inhibitory effects of individual isothiocyanates prevalent in each crucifer species [75]. Phenylethyl isothiocyanate (PEITC, Fig. 16.1), the hydrolytic metabolite of gluconasturitiin (watercress's principal glucosinolate) and an inhibitor of murine CYP2E activity, was believed responsible for inhibition of human CYP2E1 [78]. For broccoli, whose principal isothiocyanate, sulforaphane, possesses a methylsulfinylbutyl side chain (Fig. 16.1), the induction of CYP1A2 seemed linked to sulforaphane exposure [39]. Moreover, both PETIC and sulforaphane appeared to stimulate UGT activity. From these early studies, it became clear that cruciferous vegetables exert differential effects on XMEs—inhibiting some isoforms while inducing others—and these outcomes depend on the type and quantity of glucosinolates present in each crucifer form.

The last decade has seen a modest increase in the number of clinical trials assessing the impact of cruciferous vegetables on human drug metabolism. In a series of healthy volunteer studies evaluating diets containing broccoli (~300 g/meal), brussels sprouts

Figure 16.1 Representative phytochemicals (isothiocyanates) present in cruciferous vegetables.

(~300 g/meal), cauliflower (~300 g/meal), cabbage (~150 g/meal), and radish sprouts (~32 g/meal), significant increases in phenotypic measures of CYP1A2 [81,82] and UGT1A1 [83] activity, as well as elevated concentrations of GSTA1 and GSTM1 [84–87], were consistently observed. An investigation utilizing isolated human jejunal segments (Loc-I-Gut procedure) found that sulforaphane produced rapid (~2 h) and significant (approximately twofold) increases in GSTA1 and UGT1A1 mRNA from exfoliated enterocytes [88]. Collectively, these findings bolster numerous *in vitro* and animal studies that specific isothiocyanates can function as ligands for nuclear receptors that upregulate CYP1A2 (i.e., AhR) [89] and various transferases (i.e., nuclear factor erythroid-2 related factor 2, Nrf2) [39,90].

Interestingly, sulforaphane also downregulates CYP3A4 expression in human primary hepatocytes [91,92], purportedly by acting as a selective antagonist for PXR [93]. As the only natural PXR antagonist discovered to date, sulforaphane effectively impedes PXR-mediated CYP3A4 expression *in vitro* [93]. While yet to be confirmed *in vivo*, this last activity may not only represent another mechanism for sulforaphane chemoprevention, but may reduce adverse drug responses that arise through induction of *CYP3A4* and other PXR target genes.

Although not as intensively studied as their effects on XMEs, *in vitro* methods identify isothiocyanates as both substrates and inhibitors of ABC efflux transporters [94–96]. As inhibitors, however, they are not especially potent. Since isothiocyanate concentrations in excess of 50 μ M are necessary for *in vitro* inhibition (levels rarely achieved in the normal diet), the clinical risk for crucifer-ABC transporter interactions appears minimal.

In summary, when consumed in sufficient quantities, cruciferous vegetables can modulate XME activity; however, the amounts administered in the studies described above far exceed those commonly encountered in normal diets. Thus, with customary usage, the risk for clinically important crucifer–drug interactions seems limited.

Interaction risk: Low.

16.5.2 Citrus Juices

Unlike cruciferous vegetables, whose phytochemicals may affect human drug metabolism when consumed in excess, certain citrus fruit juices, especially grapefruit juice, pose a greater risk for food–drug interactions. Grapefruit juice (GFJ, *Citrus paradisi*) increases the oral bioavailability (a pharmacokinetic parameter designated by the letter *F*) of many drugs that are CYP3A4 substrates [97–99]. This effect was first observed two decades ago when concurrent administration of GFJ with either felodipine or nifedipine increased the area under the plasma concentration–time curve (AUC) for these two calcium channel blockers by more than 250% and 135%, respectively [100,101] (Fig. 16.2). The clinical relevance of this interaction was heightened by the occurrence of adverse hemodynamic side effects. Since that time, considerable research into the effects of citrus juices on drug disposition has been conducted making it the most widely studied food–drug interaction to date, with more than 350 scientific articles on GFJ-related interactions alone. From these efforts, a clearer understanding of the mechanisms underlying these interactions and their clinical relevance has come into view [42,99,102–104].

It is now recognized that fruits of various citrus plants (Rutaceae) produce a group of phytochemicals known as *linear furanocoumarins* (psoralens) (Fig. 16.3), which

Figure 16.2 Effect of grapefruit juice on mean felodipine plasma concentrations. Felodipine plasma concentrations after the oral administration of 10-mg felodipine with either water (●), a single 8-oz. glass of grapefruit juice (○), or after five days of thrice daily administration of grapefruit juice (Δ). Bars indicate standard errors. Reprinted with permission. Ref. 100.

are mechanism-based inhibitors of CYP3A4 [43,105,106]. Those furanocoumarins most important for CYP3A inhibition are (in order of decreasing potency) the paradisins (a group of dihydroxybergamottin dimers), 6',7'-dihydroxybergamottin, 6',7'-epoxybergamottin, and bergamottin [107,108] (Fig. 16.3). Because furanocoumarins cause rapid degradation of CYP3A4, de novo enzyme synthesis—a process often taking more than 24 h—is necessary for recovery [109]. It appears that intestinal CYP3A4 isoforms are most readily affected. As little as 10 fluid ounces of regular strength GFJ is capable of producing significant inhibition [42,99,110]; however, excessive quantities or prolonged use may influence hepatic CYP3A activity [42,111]. The magnitude of the effect is dependent on furanocoumarin exposure, which is a function of type and quantity of juice and duration of juice ingestion [42,99,105,109]. Of the citrus juices most widely consumed, GFJ is of greatest concern as it contains the highest concentrations of furanocoumarins. Even unprocessed grapefruit segments, a common breakfast item, contain enough furanocoumarins to increase absorption of several drugs [112]. Seville orange (*Citrus aurantium*, bitter orange) juice, a widely studied variety, also contains high concentrations of furanocoumarins and can increase the bioavailability of many CYP3A substrates [113,114], but its bitter taste relegates it primarily to research purposes. Aqueous extracts of *C. aurantium* containing significant quantities of the sympathomimetic agent, synephrine, are common components of many weight-loss dietary supplements, yet they pose little risk for CYP3A-mediated interactions, since the highly lipophilic furanocoumarins are not extracted due to poor water solubility [115]. Pomelo (*Citrus grandis*) juice also contains furanocoumarins, and its use has been linked to interactions involving the immunosuppressant drugs, tacrolimus [116] and cyclosporine [117]. Other citrus juices such as

Figure 16.3 Representative phytochemicals (furanocoumarins) present in grapefruit juice.

orange (*Citrus sinensis*), lemon (*Citrus limon*), lime (*Citrus aurantifolia*), and tangerine (*Citrus reticulata*) are generally lower in their furanocoumarin content, or they differ in their furanocoumarin profile and do not interact with CYP3A substrates [42,102,118]. *C. sinensis* is almost devoid of furanocoumarins while the prevalent species in *C. limon* and *C. aurantifolia* are imperatorin and isoimperatorin [118] (Fig. 16.3).

In the small intestine, furanocoumarin-mediated inhibition of CYP3A4 increases circulating levels of various drugs that may lead to an enhanced pharmacodynamic effect and possible toxicity. Drugs most affected by GFJ are CYP3A4 substrates with narrow therapeutic indices that undergo extensive presystemic intestinal metabolism [42,99,119]. Accordingly, the already low oral bioavailability (i.e., $F < 25\%$) of such drugs can be dramatically increased, oftentimes to values several fold greater than normal. Of the many compounds whose pharmacokinetic profiles are influenced by GFJ, only a few fulfill these criteria. Those medications posing the greatest risk for clinically significant GFJ-related interactions are listed in Table 16.1. These include selected calcium channel blockers, certain HMG-CoA reductase inhibitors, calcineurin-inhibitor immunosuppressants, and a variety of others [99,103]. In lieu of potentially harmful drug toxicity, the labeling for some medications includes warnings or precautionary statements regarding GFJ interaction potential [120].

To what extent citrus juices affect xenobiotic transporter function *in vivo* remains to be fully determined. Clinical evidence suggests that GFJ and other citrus juices are not potent modulators of human ABC efflux transporter activity. Support for this view stems from GFJ's inability to negatively affect the clinical pharmacokinetic profile of

TABLE 16.1 Drugs Posing Significant Risks for Clinically Important Interaction When Taken with Grapefruit Juice and Other Citrus Juices

<i>Drugs exhibiting increased oral bioavailability (grapefruit juice)</i>
Calcium channel blockers: felodipine, nifedipine, nisoldipine, nitrendipine, manidipine
HMG-CoA reductase inhibitors: atorvastatin, lovastatin, simvastatin
Calcineurin-inhibitor immunosuppressants: cyclosporine, tacrolimus, sirolimus
Others: amiodarone, buspirone, carbamazepine, cisapride, diazepam, halofantrine
<i>Drugs exhibiting reduced oral bioavailability (grapefruit juice, orange juice, others)</i>
Fexofenadine, cefiprolol
